EDITOR : J. M. BROWNE KUTSCHBACH, M.B., D.P.H.

VOLUME THE FORTY-FIRST

JANUARY—DECEMBER 1948

(Session October 1947—September 1948)

LONDON
LONGMANS, GREEN & CO., LTD., 6 & 7, CLIFFORD STREET, W.1.

1948

PROCEEDINGS

OF THE

ROYAL SOCIETY OF MEDICINE

EDITED UNDER THE DIRECTION OF THE EDITORIAL COMMITTEE

HONORARY EDITORS: ERIC A. CROOK, M.Ch., and E. R. CULLINAN, M.D.

EDITOR: J. M. BROWNE KUTSCHBACH, M.B., D.P.H.

VOLUME THE FORTY-FIRST

SESSION 1947-48

OFFICERS:

President—Sir MAURICE CASSIDY, K.C.V.O., M.D.

Immediate Past-President—Sir GORDON GORDON-TAYLOR, K.B.E., M.S.

Vice-Presidents—(Being the Presidents or duly appointed Representatives of the Sections the names of which are given in brackets)—J. H. T. CHALLIS (Anæsthetics); G. E. VILVANDRÉ (Clinical); R. E. GLOVER, F.R.C.V.S. (Comparative Medicine); J. E. M. WIGLEY, F.R.C.P. (Dermatology); L. R. BROSTER, O.B.E., M.Ch. (Endocrinology); W. S. C. COPEMAN, O.B.E., F.R.C.P. (Epidemiology and State Medicine); H. P. HIMSWORTH, M.D. (Experimental Medicine and Therapeutics); HUBERT J. NORMAN, M.B. (History of Medicine); C. GILL-CAREY, F.R.C.S.Ed. (Laryngology); MAURICE DAVIDSON, M.D. (Medicine); C. WORSTER-DROUGHT, M.D. (Neurology); A. J. McNAIR, F.R.C.S. (Obstetrics and Gynaecology); ARTHUR BULLEID, L.R.C.P., M.R.C.S., L.D.S.E., (Odontology); HAROLD LEVY, F.R.C.S. (Ophthalmology); GEORGE PERKINS, M.C., F.R.C.S. (Orthopædics); F. C. ORMEROD, F.R.C.S. (Otolaryngology); W. G. WYLLIE, M.D. (Pædiatrics); A. B. ROSHER (Pathology); W. S. TEGNER, M.R.C.P. (Physical Medicine); A. DICKSON WRIGHT, M.S. (Proctology); Professor AUBREY LEWIS, M.D. (Psychiatry); HUGH DAVIES, D.M. (Radiology); Sir MAX PAGE, K.B.E., M.S. (Surgery); A. CLIFFORD MORSON, O.B.E., F.R.C.S. (Urology).

Honorary Treasurers—C. E. NEWMAN, M.D.; L. R. BROSTER, O.B.E., M.Ch.

Honorary Secretaries—W. A. POOL, M.R.C.V.S.; A. T. M. WILSON, M.D.

Honorary Librarians—E. K. MARTIN, M.S.; T. C. HUNT, D.M.

Honorary Editors—ERIC A. CROOK, M.Ch.; E. R. CULLINAN, M.D.

Other Members of Council—GERALDINE M. BARRY, F.R.C.S.; E. R. BOLAND, C.B.E., F.R.C.P.; Sir ERNEST ROCK CARLING, F.R.C.S.; E. A. COCKAYNE, D.M.; V. ZACHARY COPE, M.S.; MACDONALD CRITCHLEY, M.D.; MAURICE DAVIDSON, M.D.; DANIEL T. DAVIES, C.V.O., M.D.; CHARLES DONALD, O.B.E., Ch.M.; CHARLES HARRIS, M.D.; JOHN B. HUNTER, C.B.E., M.Ch.; H. L. MARRIOTT, C.B.E., M.D.; M. F. NICHOLLS, C.B.E., M.Ch.; R. H. O. B. ROBINSON, F.R.C.S.; A. C. ROXBURGH, M.D.; Sir HENRY TIDY, K.B.E., M.D.

JOINT DISCUSSIONS

SECTION OF ENDOCRINOLOGY AND SECTION OF PÆDIATRICS (JOINT DISCUSSION No. 1)

Proceedings VOL. XLI
June

Meeting March 24, 1948

PAGE
Volume

TWO BROTHERS WITH INFANTILISM, SHOWING SOME FEATURES OF PROGERIA,
ASSOCIATED WITH MICROCEPHALY, RETINAL DEGENERATION AND INTRA-
CRANIAL CALCIFICATION

Catherine A. Neill, M.D., and M. M. Dingwall (for Helen M. M.
Mackay, F.R.C.P.)

349

THREE CASES OF PRECOCIOUS PUBERTY

N. F. Elliott Burrows, B.M. (for W. G. Wyllie, M.D.)

350

OBESITY, HYPOGONADISM, HYPOTHYROIDISM, ADENOMA OF THYROID
GLAND AND FAILURE OF GROWTH IN A GIRL AGED 13 YEARS

Raymond Greene, D.M.

352

DIABETES INSIPIDUS

J. P. M. Tizard, M.R.C.P. (for W. G. Wyllie, M.D.)

352

SECTIONS OF MEDICINE, RADIOLOGY AND SURGERY (JOINT DISCUSSION No. 2)

July

Meeting February 24, 1948

DISCUSSION ON CHRONIC DISEASES OF THE PERICARDIUM

431-442

Dr. B. T. Parsons-Smith

431

Mr. T. Holmes Sellors [*Abstract*]

435

Dr. Peter Kerley

437

THE INFLUENCE OF THE SMALL ANIMAL BREEDER ON BIOLOGICAL RESEARCH. [Abridged]

President's Address by R. E. Glover, F.R.C.V.S. 1 85

May

Meeting December 10, 1947

DISCUSSION ON NUTRITION AND RESISTANCE TO INFECTION	9-14	323-328
Dr. P. G. H. Gell	9	323
Mr. Herbert Parry	10	324
Dr. Z. A. Leitner	12	326
Dr. J. W. Howie	13	327
Sir Percival Hartley	14	328

May

Meeting February 18, 1948

DISCUSSION ON SWINE ERYSIPELAS INFECTION (<i>ERYSIPELO- THRIX RHUSIOPATHIÆ</i>) IN MAN AND ANIMALS	14-18	328-332
Dr. Mary Barber	14	328
Mr. A. W. Gledhill	16	330

July

Meeting March 17, 1948

DISCUSSION ON STAPHYLOCOCCAL INFECTIONS	19-22	427-430
Professor Wilson Smith	19	427
Dr. V. D. Allison, Dr. A. McDiarmid	21	429

August

Meeting April 21, 1948

WITH THE ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE

DISCUSSION: THE EPIDEMIOLOGY OF TRYPANOSOMIASIS IN MAN AND ANIMALS.. .. .	23-30	551-558
Dr. J. Carmichael	23	551
Dr. Cecil A. Hoare	25	553
Dr. J. T. Edwards	27	555
Brigadier J. S. K. Boyd, Dr. E. M. Lourie	29	557
Dr. F. Hawking, Dr. P. L. LeRoux, Dr. C. A. Hoare	30	558

The Society does not hold itself in any way responsible for the statements made or the views put forward in the various papers.

PIGMENTED PURPURIC LICHENOID DERMATITIS OF GOUGEROT AND BLUM E. W. Prosser Thomas, M.D., and Arthur Rook, M.R.C.P.	24	530

List of other Cases shown	26	532

November

Meeting April 15, 1948

MODERN CONCEPTIONS CONCERNING THE COMPULSORY ISOLATION OF LEPERS. CONTAGIOUS MALIGNANT MORBUS HANSEN <i>versus</i> NON-CONTAGIOUS BENIGN HANSENIDE R. D. G. Ph. Simons, M.D.	27	751
SCHANBERG'S DISEASE H. W. Barber, F.R.C.P.	30	754
PARAPSORIASIS EN PLAQUES TREATED WITH CALCIFEROL H. W. Barber, F.R.C.P., and David Erskine, M.D.	31	755
PARAPSORIASIS EN PLAQUES—TREATED WITH VITAMIN D ₂ Allan Yorke, M.R.C.S., L.R.C.P.	31	755
MULTIPLE ATROPHIC LESIONS: CASE FOR DIAGNOSIS C. D. Evans, M.B.	32	756
FOX-FORDYCE DISEASE IN A YOUNG GIRL R. T. Brain, M.D.	33	757
NECROBIOSIS LIPOIDICA DIABETICORUM FOLLOWING PYODERMA F. Ray Bettley, F.R.C.P.	33	757
SARCOIDOSIS FOLLOWING INJURY F. Ray Bettley, F.R.C.P.	34	758
INCONTINENTIA PIGMENTI (BLOCH SULZBERGER) Henry Haber, M.D.	35	759
List of other Cases shown	35	759

November

Meeting May 20, 1948

PRECOCITY IN A GIRL AGED 5: DUE TO STILBCESTROL INUNCTION C. H. Whittle, M.D., and A. Lyell, M.B.	36	760
EPIDERMOLYSIS BULLOSA, TWO CASES (FATHER AND SON) David I. Williams, M.R.C.P.	36	760
TROPICAL LICHENOID DERMATITIS K. Greenwood, M.B., M.R.C.P., Major R.A.M.C.	37	761
List of other Cases shown	37	761

November

Meeting June 17, 1948

PRETIBIAL MYXOMATOUS DEGENERATION C. D. Calnan, M.B. (for I. Muende, M.R.C.P.)	38	762
EPIDERMOLYSIS BULLOSA DYSTROPHICA (WITH "ALBOPAPULOID DYSTROPHY" OF PASINI) C. H. Whittle, M.D., and A. Lyell, M.B.	38	762
HYPERKERATOSIS FOLLICULARIS ET PARAFOLLICULARIS IN CUTEM PENETRANS (KYLE) Ronald Scutt, M.B. (for R. M. B. MacKenna, M.D.)	39	763
List of other Cases shown	40	764

EPIDERMOLYSIS BULLOSA ACQUISITA

H. W. Barber, F.R.C.P. 1 105

LICHEN SCLEROSUS ET ATROPHICUS TREATED WITH VITAMIN E

R. M. B. MacKenna, M.D., and Brian F. Russell, M.D. 2 106

CASE FOR DIAGNOSIS. ? POIKILODERMIA OF CIVATTE

R. T. Brain, M.D. 3 107

List of other Cases shown 4 108

February

Meeting November 20, 1947

(?) ECZEMATOID TUBERCULIDE

H. W. Barber, F.R.C.P. 5 109

GOLD DERMATITIS, TREATED WITH B.A.L. TOXIC MANIFESTATIONS ? RELATED
TO CALCIUM DEPRIVATION

Bernard Green, M.R.C.S., L.R.C.P., and Brian F. Russell, M.D. 6 110

List of other Cases shown 8 112

May

Meeting December 18, 1947

RHEUMATIC NODULES: GRANULOMA ANNULARE

R. E. Bowers, M.B. 9 299

ACNE CONGLOBATA TREATED BY IMPLANTATION OF 300 MG. OF STILBCESTROL

L. Forman, M.D. 10 300

SUBCUTANEOUS NODULES: FOR DIAGNOSIS. ? GRANULOMA ANNULARE

J. P. M. Tizard, M.R.C.P. (for Professor A. A. Moncrieff) 11 301

List of other Cases shown 13 303

May

Meeting January 15, 1948

HISTIOCYTOMA

Alice Carleton, M.D. 13 303

DERMATITIS (FLAVINE) TREATED WITH LARGE DAILY DOSES OF CRUDE LIVER

Brian Russell, M.D. 13 303

SEBORRHOIC DERMATITIS WITH EXACERBATION FROM ACRIFLAVINE

Brian Russell, M.D. 13 303

DERMATITIS (SULPHONAMIDE) TREATED WITH LARGE DAILY DOSES OF CRUDE
LIVER

Brian Russell, M.D. 14 304

DERMATITIS (FLAVINE) TREATED WITH LARGE DAILY DOSES OF CRUDE LIVER

Brian Russell, M.D. 14 304

LEPROSY

A. J. Suchett-Kaye, M.D. (for A. H. Harkness, M.R.C.S.) 16 306

List of other Cases shown 17 307

May

Meeting February 19, 1948

PUSTULAR ERUPTION: FOR DIAGNOSIS

J. R. Simpson, M.B., M.R.C.P. 17 307

TROPICAL LICHENOID DERMATITIS

P. D. Samman, M.R.C.P. (for S. Hardy Kingston, M.B.) 18 308

LEPROSY TREATED WITH SULPHETHRONE IN 1943

A. H. Harkness, M.R.C.S., L.R.C.P., and G. Brownlie, Ph.D. 19 309

ERYTHEMA ELEVATUM DIUTINUM

Dr. E. Lipman Cohen 20 310

August

Meeting March 18, 1948

POLYARTHRITIS WITH DERMATITIS. ? KERATODERMIA BLENNORRHAGICA
(Dr. Philip Ellman's Case)

David Weitzman, M.D., M.R.C.P. (for J. E. M. Wigley, F.R.C.P.) 21 527

XANTHOMA TUBEROSUM MULTIPLEX

James Overton, M.D. 22 528

PURPURA WITH CAPILLARY FRAGILITY

H. W. Barber, F.R.C.P., and J. D. Everall, M.R.C.S., L.R.C.P. 23 529

PIGMENTED PURPURIC LICHENOID DERMATITIS OF GOUGEROT AND BLUM E. W. Prosser Thomas, M.D., and Arthur Rook, M.R.C.P.	24	530
PRIMARY FOCUS OF TUBERCULOUS INFECTION IN THE SKIN R. M. B. MacKenna, M.D.	25	531
List of other Cases shown	26	532

November

Meeting April 15, 1948

MODERN CONCEPTIONS CONCERNING THE COMPULSORY ISOLATION OF LEPERS. CONTAGIOUS MALIGNANT MORBUS HANSEN versus NON-CONTAGIOUS BENIGN HANSENIDE R. D. G. Ph. Simons, M.D.	27	751
SCHAMBERG'S DISEASE H. W. Barber, F.R.C.P.	30	754
PARAPSORIASIS EN PLAQUES TREATED WITH CALCIFEROL H. W. Barber, F.R.C.P., and David Erskine, M.D.	31	755
PARAPSORIASIS EN PLAQUES—TREATED WITH VITAMIN D ₂ Allan Yorke, M.R.C.S., L.R.C.P.	31	755
MULTIPLE ATROPHIC LESIONS: CASE FOR DIAGNOSIS C. D. Evans, M.B.	32	756
FOX-FORDYCE DISEASE IN A YOUNG GIRL R. T. Brain, M.D.	33	757
NECROBIOSIS LIPOIDICA DIABETICORUM FOLLOWING PYODERMA F. Ray Bettley, F.R.C.P.	33	757
SARCOIDOSIS FOLLOWING INJURY F. Ray Bettley, F.R.C.P.	34	758
INCONTINENTIA PIGMENTI (BLOCH SULZBERGER) Henry Haber, M.D.	35	759
List of other Cases shown	35	759

November

Meeting May 20, 1948

PRECOCITY IN A GIRL AGED 5: DUE TO STILBGESTROL INUNCTION C. H. Whittle, M.D., and A. Lyell, M.B.	36	760
EPIDERMOLYSIS BULLOSA, TWO CASES (FATHER AND SON) David I. Williams, M.R.C.P.	36	760
TROPICAL LICHENOID DERMATITIS K. Greenwood, M.B., M.R.C.P., Major R.A.M.C.	37	761
List of other Cases shown	37	761

November

Meeting June 17, 1948

PRETIBIAL MYXOMATOUS DEGENERATION C. D. Calnan, M.B. (for I. Muende, M.R.C.P.)	38	762
EPIDERMOLYSIS BULLOSA DYSTROPHICA (WITH "ALBOPAPULOID DYSTROPHY" OF PASINI) C. H. Whittle, M.D., and A. Lyell, M.B.	38	762
HYPERKERATOSIS FOLLICULARIS ET PARAFOLLICULARIS IN CUTEM PENETRANS (KYRLE) Ronald Scutt, M.B. (for R. M. B. MacKenna, M.D.)	39	763

DISCUSSION ON THE ASSOCIATION OF OTITIS MEDIA WITH ACUTE NON-SPECIFIC GASTRO-ENTERITIS OF INFANTS

Miss Winifred Hall: Acute non-specific gastro-enteritis of infants, or the diarrhoea and vomiting syndrome, as it is also called, is recognized as a condition limited to the first twelve months of life. That is not to say that older children do not suffer from diarrhoea and vomiting, but the character of the disease and the behaviour of the patient are then quite different from what is seen in the infant. In infancy, the dominant feature of the severe case is the appalling dehydration, which may occur either with the primary disease, or as the herald of the onset of a parenteral infection. In the toddler and older children, dehydration is absent. Why this should be, we do not know. Whether we are dealing with a specific infection, bacterial or virus, but limited in its application to the first year of life, or whether it is something inherent in the gradually evolving economy of the young infant, has yet to be decided. Quite possibly it is a mixture of both factors. It is certain that the younger the infant, the more typical is the course of the illness, and after roughly 10 months of age the response of the child to its infection tends to approximate more and more to that of its elders. This means, therefore, that the approach of the doctor, which includes the otologist, to the problems of infantile gastro-enteritis must be quite different from his approach to illness in an older child.

† In Table I the incidence and mortality of cases admitted to the North-Western Hospital in

(to June 6)

the different age-groups during the years 1942-47 are shown, and the falling off of admissions in the later groups is very noticeable. The table also shows the very marked improvement in mortality figures in the later years. In 1942 the mortality rate was 39%. In 1943 it dropped to 13%. In 1943 the otitis media figures were 40% of all cases, yet you will notice that only 12 mastoid operations were done that year. In 1945 there were 24 operations; in 1946, 6; while for the first six months of 1947 there have been none. But, although both the otitis media rate and the mortality rate have fallen, the severity of the disease has in no way declined. The improvement is entirely due to better methods of general treatment, plus earlier recognition and more vigorous treatment of associated parenteral infections.

During the years 1942-47 I was attached to six hospitals in widely separated areas, and was therefore able to observe not only variations in the disease in the different localities, but also the results of varying paediatric treatments. Four of these hospitals were in London, and two at St. Albans. The total number of mastoid operations done during these years is 190, and several hundred more cases of otitis media were seen which recovered without operation.

The work on these cases began originally with the theory that the condition was a primary mastoiditis with a secondary irritative gastro-enteritis, a theory which has been postulated by various observers, and so in the early cases, all which failed to respond quickly to treatment proceeded to operation. We had, therefore, two main ideas in mind: (1) To

The Society does not hold itself in any way responsible for the statements made or the views put forward in the various papers.

pearance. A pink, or red, flush without fullness is not usually an indication for myringotomy; with adequate treatment such a drum may return to normal. It does indicate an incipient infective process that needs watching. I would consider the indications for myringotomy to be: (1) A localized grey or red posterior bulge; (2) a generalized red bulging drum; (3) a grey opaque bulging drum; and (4) a red flushed drum without fullness, but associated with pyrexia or an exacerbation of the general symptoms.

In the infant, the eustachian tube is short and straight. Cases have been recorded where milk has been found in the middle-ear cavity at operation. It is therefore important clinically that the babies should not be fed lying on their backs.

My first group of cases occurred in the latter part of 1942 at Oster House E.M.S. Hospital, St. Albans. At that time ordinary otitic conditions were very prevalent, and when our first cases showed a purulent otitis media early in the illness, and rapidly went on to operation with positive results, it did look as though the gastro-enteritis was merely the infant's way of responding to an otitic invasion. But as the series proceeded, and I began to extend my observations to other hospitals, it soon became obvious that this was not the case, and that the otitis was only an incidental factor in the disease. The onset of other parenteral infections produced exactly the same gastro-enteritic reactions as did the otitis.

The Oster House children were all examined aurally on admission. An abnormal drum was incised as soon as it appeared. Intravenous drips were used for the dehydration, but if no improvement occurred in forty-eight hours, we proceeded to a bilateral mastoidectomy. The reason for this was as follows: We found that in almost all cases of true infection, both mastoids were involved; and, further, the contents of the mastoids often bore no relation to the appearance of the drum. Often what appeared to be the better ear had the worse mastoid on operation.

Because of the absence of typical signs, the diagnosis of a mastoid infection and the decision when to operate can be extremely difficult. One of the most trying things from the surgeon's point of view is the way in which a purulent otitis will dry up. It is quite common to find a bulging drum, obtain pus on myringotomy with relief to the symptoms, and then have another general relapse in a few days' time. On examination the original incision is soundly healed, and the drum again red and bulging. In the early days I would have operated with such a history. Nowadays, I would not unless the child's condition continued to deteriorate in spite of treatment. I think that a certain amount of pus must escape down the eustachian tube, and after the immediate tension has been relieved by a myringotomy, the drum will therefore heal. If, later on, another sudden collection of pus occurs, the process is repeated. The myringotomies do not seem to have any untoward after-effects, and it is not necessary to open the mastoid after two or even three incisions, unless the general condition fails to respond. It must be remembered that a collection of pus in the middle ears can appear quite suddenly, and be accompanied by equally sudden symptoms. Within a few hours a normal drum can become red and bulging, and a fairly well baby become acutely shocked and dehydrated, with a disconcerting increase in its diarrhoea and vomiting; particularly its diarrhoea. At the same time it must not be forgotten that otitis is not the only infection that will cause these sudden general signs; pneumonia, for example, is a very common cause, and in cases where the indications are not clear, other infections must be excluded before placing the blame on the ears. If, after excluding everything else, there is still a doubt about the ears, they should be explored. The risk of a quick exploration, with a local anæsthetic, is very much less than the risk of an undrained infection.

The indications for operation are:

- (1) Persistent pyrexia.
- (2) Persistent, or increasing diarrhoea; this is a much more reliable indication than vomiting.
- (3) Sudden, or recurrent dehydration.
- (4) Persistent failure to improve; without dramatic collapses.

Associated with a history of recent positive myringotomies.

- (5) Persistent, possibly profuse, otorrhoea associated with any of the above.

If any of the above persist in spite of strenuous general and anti-infective measures, then the mastoids should be opened.

- (6) As an exploratory measure in refractory cases, where no cause can be found for the symptoms, to exclude the possibility of a silent mastoid, remembering that with modern methods of treatment these cases are nowadays very rare.

Operative Procedure.

Until 1944, I operated with general anæsthesia, but it was found that no matter what the anæsthetic, chest complications were not uncommon; the babies tended to be collapsed afterwards, and took longer to recover, and the resumption of normal feeding was delayed.

determine whether in the acutely ill baby a mastoid infection was always to be found ; (2) To find out whether operation did or did not bring about improvement.

We soon found that the idea of a primary mastoid infection was untenable. By no means all severely ill babies even have an otitis media. But in those cases which had a mastoiditis, particularly where frank pus was found, improvement after operation was immediate and often dramatic.

In small babies the textbook signs of acute mastoiditis are completely absent. There is never any redness or swelling, and as a sick baby cries with any handling, it is quite impossible to know whether tenderness is present or not. The head-rolling sign, so often quoted, is quite unreliable, and so is enlargement of the posterior cervical group of glands. The drumhead signs can also differ from those of acute otitis in an older patient, due to differences in the anatomy of the infantile ear. It is advisable, therefore, before going on to the clinical aspect to consider these anatomical peculiarities, and the resultant difficulties in examination.

Anatomical Points.

One of the most important points is that in the infant the meatal canal runs downwards and forwards at an inclination of 35 degrees, so that in introducing a speculum one sees first of all the posterior and superior parts of the drum, and to see the anterior portion, it is necessary to tilt the speculum quite considerably. Ignorance of this can be a very real pitfall for those unaccustomed to the infant ear. Another point is that the calibre of the canal varies from the extremely narrow to the respectably wide; a variation peculiar to the individual, and in no way connected with his age.

In Lederer's "Diseases of the Ear, Nose and Throat" (1946 Ed., Philadelphia), we are told that in order to see the drum the speculum must be inserted until it nearly reaches the membrana. This is quite unnecessary, and will only cause damage to the meatal wall and drive the wax which is always present down on to the drum. A small speculum, carefully inserted and moved so as to show all parts of the drum in turn is all that is required. Wax is always present in the meatus in varying amounts. It must be completely removed before an accurate picture of the drumhead can be obtained, and this can be a very slow and difficult procedure. I personally use either a specially made fine hook, with a carefully rounded end, or the wool-carrying end of a very fine Jobson Horne wool carrier.

Contrary to the textbook statements the normal infant drumhead should show a properly formed light reflex, after about 6 weeks of age. It is usually shorter and fatter than in the adult, but it is quite definitely present, and absence means that the drum should be watched. Absence is not an indication for myringotomy, but it will be found that as the child returns to normal, so the light reflex reappears. I think that the reason why it is so often said to be absent in the infant is due partly to the anatomical difficulty of seeing that area of the drum, and partly to the difficulty of completely removing the wax. It is very easy to mistake a thin colourless deep-lying sheet of wax for the drum.

The tympanic membrane of an infant is said to be thicker than in later life. This is only so in the very young infant of the 1 to 6 weeks age-group; it is certainly not so in older babies. In the early days when we were doing many myringotomies as diagnostic measures in cases of unexplained pyrexia, or persistent toxæmia, one sometimes went through a thick opaque membrane, and had a dry puncture, while in other children of the same age-group, the drum would be quite thin, and the knife go through with the characteristic sound and feel of parchment. There does not seem to be any definite age when the change in character of the drum takes place; it seems to be an individual matter. The thick drums do not, of course, show a light reflex.

In the young infant there persists an undifferentiated mass of mesenchymal tissue in the upper part of the middle ear, often with trabeculae passing downwards to other points in the cavity. This mass partly shuts off the lower and anterior parts of the middle ear, and it is quite possible that it accounts for at least some of the cases of mastoiditis with an apparently normal drum. These cases, by the way, are not common, but they do occur, and the possibility of a completely "silent" mastoid must be remembered when searching for the cause of a persistent pyrexia, or a sudden collapse. It probably does account for the frequency with which one meets a suppurative otitis media confined to the upper and posterior part of the tympanic cavity. The auriscopic appearances in such cases are typical. There is an elongated red shining bulge along the posterior meatal wall, more marked above than below. On looking round, the drum proper appears to be lying on a much deeper plane, and often appears perfectly normal, even to the possession of a light reflex. The inexperienced observer is apt to assume that he is looking at a posterior wall furuncle. Actually the forward bulge of the posterior part of the drum carries with it the adjacent part of the posterior meatal wall, and it is often very difficult to make out where one ends and the other begins.

The appearance of the inflamed drumhead may vary from a faint greyish-red flush either at the margin, or spread over the surface, to the typical bulging bright red drum. Sometimes a tense collection of pus gives the drum a characteristic opaque grey colour, and full ap-

pearance. A pink, or red, flush without fullness is not usually an indication for myringotomy; with adequate treatment such a drum may return to normal. It does indicate an incipient infective process that needs watching. I would consider the indications for myringotomy to be: (1) A localized grey or red posterior bulge; (2) a generalized red bulging drum; (3) a grey opaque bulging drum; and (4) a red flushed drum without fullness, but associated with pyrexia or an exacerbation of the general symptoms.

In the infant, the eustachian tube is short and straight. Cases have been recorded where milk has been found in the middle-ear cavity at operation. It is therefore important clinically that the babies should not be fed lying on their backs.

My first group of cases occurred in the latter part of 1942 at Oster House E.M.S. Hospital, St. Albans. At that time ordinary otitic conditions were very prevalent, and when our first cases showed a purulent otitis media early in the illness, and rapidly went on to operation with positive results, it did look as though the gastro-enteritis was merely the infant's way of responding to an otitic invasion. But as the series proceeded, and I began to extend my observations to other hospitals, it soon became obvious that this was not the case, and that the otitis was only an incidental factor in the disease. The onset of other parenteral infections produced exactly the same gastro-enteritic reactions as did the otitis.

The Oster House children were all examined aurally on admission. An abnormal drum was incised as soon as it appeared. Intravenous drips were used for the dehydration, but if no improvement occurred in forty-eight hours, we proceeded to a bilateral mastoidectomy. The reason for this was as follows: We found that in almost all cases of true infection, both mastoids were involved; and, further, the contents of the mastoids often bore no relation to the appearance of the drum. Often what appeared to be the better ear had the worse mastoid on operation.

Because of the absence of typical signs, the diagnosis of a mastoid infection and the decision when to operate can be extremely difficult. One of the most trying things from the surgeon's point of view is the way in which a purulent otitis will dry up. It is quite common to find a bulging drum, obtain pus on myringotomy with relief to the symptoms, and then have another general relapse in a few days' time. On examination the original incision is soundly healed, and the drum again red and bulging. In the early days I would have operated with such a history. Nowadays, I would not unless the child's condition continued to deteriorate in spite of treatment. I think that a certain amount of pus must escape down the eustachian tube, and after the immediate tension has been relieved by a myringotomy, the drum will therefore heal. If, later on, another sudden collection of pus occurs, the process is repeated. The myringotomies do not seem to have any untoward after-effects, and it is not necessary to open the mastoid after two or even three incisions, unless the general condition fails to respond. It must be remembered that a collection of pus in the middle ears can appear quite suddenly, and be accompanied by equally sudden symptoms. Within a few hours a normal drum can become red and bulging, and a fairly well baby become acutely shocked and dehydrated, with a disconcerting increase in its diarrhoea and vomiting; particularly its diarrhoea. At the same time it must not be forgotten that otitis is not the only infection that will cause these sudden general signs; pneumonia, for example, is a very common cause, and in cases where the indications are not clear, other infections must be excluded before placing the blame on the ears. If, after excluding everything else, there is still a doubt about the ears, they should be explored. The risk of a quick exploration, with a local anæsthetic, is very much less than the risk of an undrained infection.

The indications for operation are:

- | | |
|---|---|
| (1) Persistent pyrexia. | } Associated with a history of recent positive myringotomies. |
| (2) Persistent, or increasing diarrhoea; this is a much more reliable indication than vomiting. | |
| (3) Sudden, or recurrent dehydration. | |
| (4) Persistent failure to improve; without dramatic collapses. | |

(5) Persistent, possibly profuse, otorrhoea associated with any of the above.

If any of the above persist in spite of strenuous general and anti-infective measures, then the mastoids should be opened.

(6) As an exploratory measure in refractory cases, where no cause can be found for the symptoms, to exclude the possibility of a silent mastoid, remembering that with modern methods of treatment these cases are nowadays very rare.

Operative Procedure.

Until 1944, I operated with general anæsthesia, but it was found that no matter what the anæsthetic, chest complications were not uncommon; the babies tended to be collapsed afterwards, and took longer to recover, and the resumption of normal feeding was delayed.

I therefore started using 1% procaine as a local anaesthetic with some sort of premedication. Various drugs were tried, nembutal, seccional, chloral, but all were uncertain in their action, particularly if the child was still vomiting. The textbook dose of chloral as 1 grain per year of life is too small; the infant can tolerate much more than this. Chloral has one big disadvantage: occasionally it has a delayed reaction, and the child suddenly becomes pale, collapsed, and almost comatose two or three hours after it has been given. Seccional is the most satisfactory of oral sedatives. Nowadays, I use none of these but give morphia in the proportion of 1/40 grain per 14 lb. (0.00025 gramme per kilo) of body-weight. To give 1/40, for example, 1/4 grain (0.016 gramme) is dissolved in 10 c.c. water, and 1 c.c. is injected. It is essential to see that adequate time is allowed for the morphia to act before the child is taken to the theatre, and also that it is not disturbed in any way.

If two or three minims of adrenaline are added to the procaine, a bloodless field is obtained. 1 c.c. of procaine is used for each side. After injecting the superficial tissues the needle is plunged straight down on to the bone to infiltrate the periosteum. This can then be dissected off the bone and not scraped off. The baby does not mind a well-infiltrated periosteum being dissected away, but it does object to scraping.

Using a Bard-Parker number 18 knife a straight incision about an inch long should be made close to the post-auricular sulcus, and well above the mastoid tip. A longer incision than this only exposes an unwanted area of bone, and provided a sufficiently small retractor is used, the exposure is adequate. The subsequent scar is practically invisible, whereas if the usual long curved incision is made the result is both obvious and ugly. The bone must be opened widely; mere drainage down to the antrum is not enough. I have seen cases where this has been done without relief, and subsequent reopening showed extensive disease still present. The anatomical findings in these mastoids vary considerably, but it is evident that pneumatization can occur at a much earlier age than is taught. I have seen a completely pneumatized mastoid at 4 months old. The zygomatic cells seem to be the first to appear, and the apical cell the last. I have seen pneumatization in the zygomatic area at 4 weeks old.

I do not suture the wounds at all, but pack with half-inch ribbon gauze steeped in katiodine and parasepsin emulsion. Parasepsin is active against the usual pyogenic organisms, while katiodine, an electro-positive solution of iodine, is said to be active against the Gram-negative group, particularly the coliforms. This is most useful because of the frequency with which the latter appear either as contaminants or as active agents.

In that early series at St. Albans, we went very largely on failure to respond after forty-eight hours. All the babies were gravely ill on admission. The first 2 cases were not operated on, but at post-mortem the mastoids contained pus. The first 9 cases were done under general anaesthesia. 2 died with persistence of toxæmia and dehydration. Of the others, 4 made rapid and satisfactory recoveries after operation; the remaining 3 were held back by other infections, which in 2 of them was a post-operative pneumonia. Looking back on these cases one is struck by the fact that they were all cases of otitis media and mastoiditis from the beginning. That has by no means been the case in other series; presumably the organisms then responsible had a strong affinity for the ear. Taking all my cases, it is obvious that the idea of a primary otitis is quite untenable. In 1943-44, the otitis media rate at the North-Western Hospital was 40% of all cases. In 1945, the figures at the North-Eastern Hospital were 16%, and in 1946 29%. Although these are two different hospitals, they are all London cases, and the figures were compiled by the same observer. The fall in the number of ear infections is particularly interesting when one finds that the incidence of other parenteral infections, notably pneumonia, has not shown a corresponding fall.

Table II, which has been provided by Dr. M. Alexander of the North-Eastern Hospital

TABLE II.—NORTH-EASTERN HOSPITAL

1945 admissions	Associated with dehydration			Not associated with dehydration			Total cases
	On admission	After admission	Total	On admission	After admission	Total	
Parenteral inf.	53	27	80	70	29	99	= 179
Ot. media	10	8	18	9	10	19	= 37
Myringotomies	8	6	14	9	10	19	= 33
Mastoids	—	1	1	—	1	1	= 2

On admission = within seven days of commencement of illness.

brings out this point very well. It shows that in 1945, while there were 179 cases with some other form of parenteral infection, mostly pneumonias, there were only 37 cases of otitis media.

There is another very interesting parallel to this fall in the otitis media rate. In 1943 there was a big measles epidemic, associated with a very high otitis media rate. In the 1945 epidemic the otitis rate was low. This suggests very strongly that the otitic incidence in gastro-enteritis is a variable quantity, and fluctuates as the incidence in other diseases. In other words, if

in any given year there are at large a number of virulent organisms with a predilection for the ear, there will be a high otitis rate in diseases such as gastro-enteritis whose mode of onset is usually so devastating that the child's resistance is completely knocked out. If the attack is severe, these babies on admission are in a state of acute shock, and it is reasonable to assume that they are thereby rendered more vulnerable to whatever type of secondary infection happens to be about at the time. No doubt this variation explains why surgeons who have only recently begun to deal with these babies are not finding the mastoid infections that they had expected. Another point is that the death-rate has steadily declined. In 1942 at one hospital it was 39%; in 1946 it was 9.5%. Table III shows this very clearly.

TABLE III.—NORTH-WESTERN HOSPITAL

Year	Total admissions	Deaths	%	Mastoid operations	Deaths
1942	74	29	39	—	—
1943	147	19	12.9	12	5
1944	220	37	16.8	27	4
1945	330	54	16.3	24	9
1946	242	23	9.5	6	1
1947 (to June)	153	11	7.1	—	—

My largest series of operations at any one hospital was at the North-Western Hospital, with 69 cases for the period 1942-47. In this series there were 50 recoveries, and 19 deaths, an operation mortality rate of 27%. The cases have been classified according to the operation findings. Positive findings mean frank pus. Plus-minus means hyperæmia, or a little sticky mucus. Negative means that the ear was apparently normal. All cases had both ears opened, and the classification refers to the worse ear. As both ears were opened deliberately, irrespective of the signs, there were a certain number in which one ear was negative, but as I have already said one should never omit examination of a doubtful ear. The fact that nearly all the mastoids are bilateral is extremely interesting, and taking into consideration those cases where the infection is limited to the posterior part of the drum, there may have been in some instances at least a blood-stream infection.

Table IV shows the cause of death in the 19 fatal cases. In 10, there were no P.M. signs

TABLE IV

19 deaths

19 deaths

Causes	{	Toxæmia {	+ Operation findings, 6
			± Operation findings, 3
			- Operation findings, 1
		Pneumonia, 6 (all operation findings +)	
		Septicæmia, 3 (one with meningitis)	
			(operation findings +)

other than those of extreme toxæmia. In only one of these was there no operation evidence of otitis. The others died in spite of operation, the original infection in the toxæmic deaths, or the other parenteral infection in the others being presumably too severe to be overcome by drainage of the mastoids. It does not appear either, in looking through the notes that earlier operation could have saved the children. There is no evidence of undue delay. The post-operative progress varied. In some of the cases there was a short initial improvement, followed by a sudden collapse and rapid decline; in others there was no improvement, the child merely went on steadily deteriorating, with persistent gastro-enteritic symptoms.

Of the 50 recoveries, 3 had completely negative findings, and can be ignored. 22 made quick and convincing recoveries, while 25 recovered slowly. The 22 good cases all had mastoiditis as their only parenteral infection. 19 of them had frank pus in the mastoids. 3 of them merely showed a bony hyperæmia, but the improvement after operation was quite as rapid and convincing as in the others.

Of the 25 slow cases, 2 had to have the mastoids reopened to drain a residual area of infection, after which improvement was rapid. Of the other 23, 12 had a second parenteral infection, usually pneumonia, while in 11 no parenteral infection could be found, and the patients merely recovered slowly, with gastro-intestinal relapses of varying severity.

On the whole, figures from other hospitals agree with these. The number of negative findings was greater in the early days when we had less experience in the proper selection of cases for operation.

The conclusion to be drawn from this series is that where otitis is the only complication, an immediate and convincing recovery is to be expected. The first signs of recovery are cessation of the diarrhoea and vomiting, and no more dehydration, though this takes a little

longer to disappear. Delayed recovery after positive operation findings means either a second parenteral infection, or a degree of toxæmia too severe for the child to overcome except with difficulty.

The bacteriology of these cases is varied and confusing. Unless a secondary parenteral infection is present, many of the children go through their illness, and either die or recover without any organisms being found to account for their condition. True, they nearly all have inflamed throats, but the fact that something can always be recovered from the nasopharynx is no proof that the extremely varied and changeable flora there is responsible for the illness. Bacteriological examination of the stools and vomit has proved negative. The organisms found in the mastoids rarely coincide with those found in the throat, or even with each other. It is not at all uncommon to grow, for example, a streptococcus from one mastoid, and a pneumococcus from the other. I remember one child who grew a pure culture of *Str. viridans* from her throat. One mastoid gave a pure culture of the *Str. hæmolyticus*, and the other a pure culture of pneumococci. The child herself had a *Str. viridans* septicæmia.

The coliform bacilli play a very variable part. When a genuine pyelitis is present—not a common complication—they are usually responsible. They are often present in the nasopharynx, and are a very common contaminant on the skin surrounding the mastoid area. Hence the uselessness of penicillin as a local post-operative measure. Used by itself systemically, penicillin has been disappointing in the past. It has no effect on the gastro-enteritis itself, and will only control parenteral infection in the absence of the coliforms. We had an unpleasant instance of this at St. Albans. When penicillin first became available it was given to the gastro-enteritis cases. Unfortunately the administration coincided with the appearance of an extremely virulent strain of *B. coli*. 5 of the babies died, and we discovered too late that they were all *B. coli* septicæmias. I saw some similar cases at my other E.M.S. hospital, and there were also 2 cases at the North-Western Hospital. These 2 were fortunately discovered in time, and with sulphonamides the children recovered. The reason for the poor results with penicillin formerly, apart from coliform infections, appears to have been inadequate dosage. When the drug was first in use, 20,000 units four-hourly were considered a full dose for a 6-months-old baby. Nowadays one would give much more than that: 100,000 units six-hourly is quite a usual dose, and the response is correspondingly better.

Of the sulpha drugs all have been tried, and sulphathiazole and sulphadiazine seemed the most useful. It should be remembered that the infants' toleration for these drugs is much greater proportionately than that of the adult, and they can take surprisingly large doses. A combination of penicillin and a sulpha drug will give better results than either singly, particularly in the presence of coliforms.

Anæmia can be severe, and may greatly delay recovery. A small transfusion of whole fresh blood immediately after operation may make all the difference to the child's response.

Various investigators have suggested other sources of infection as the origin of the illness, for example the sinuses, particularly the posterior group. Others have found an œdematous condition of the brain and meninges, and have suggested that the condition is primarily an encephalitis. I have no personal knowledge of sinus findings, but cannot believe that a sinus infection is any more likely to be a primary condition than an otitis. As for the so-called encephalitis, physicians in this country, while agreeing that an œdematous appearance is often seen post mortem, do not consider that it is a true encephalitis, or that it has any causal significance.

Summary.—We still do not know the cause of acute infantile diarrhœa and vomiting. It is not bacterial, and it is not a primary mastoiditis. Many workers suspect a virus, a very tempting theory, but one which still has to be investigated. Mastoiditis undoubtedly occurs as a complication, and when the only one, response to operation is rapid and conclusive. The signs of acute otitis and mastoiditis differ in the infant from those seen in an older patient, but the effect is much more devastating, and the absence of redness and swelling must not be taken as an indication of a mild infection. If it is not treated promptly, the child will die before the stage of redness and œdema is reached.

One theory of the diarrhœa and vomiting is that it represents a "trigger response" to some stimulus. The initial one may be a virus or some other unknown quantity, but the response once started can then be elicited by any subsequent stimulus, of which otitis media is one. It takes very little to set the syndrome off once the illness has started, and a mild otitic infection could certainly do so, but a mild otitis does not as a rule go on to a mastoid infection.

An interesting point about this trigger-like irritability is that it seems to persist for some time even after apparent cure, and a baby discharged from hospital as perfectly well may be back in a few days' time as bad as ever.

Repeated myringotomy, or operation, does not appear to have any ill-effect on the hearing, unless operation has been delayed too long, in the presence of a severe infection.

I only know of two cases of severe deafness following mastoiditis, and in both of these there was an extensive bilateral purulent infection which, because of the absence of local signs, was not recognized as mastoiditis until the occurrence in one case of a facial palsy, and in the other a meningitis, superimposed upon a profuse persistent ear discharge led to the summoning of an otologist. Both these children are now at a school for the deaf.

Postscript.—The peak years for my cases were 1943 and 1944. In the first half of 1947 I saw very few cases of otitis media, and did no operations. But now, in December, it would appear that we are about to experience another upward swing in the otitis media rate. There has been a marked increase in the number of otitic cases in the last two months, and in their severity. As the occurrence of otitis media in gastro-enteritis is definitely seasonal, being at its height at the same time of year as otitis in other complaints, this strongly suggests that this winter is going to show a large number of ear complications. What effect present-day pædiatric treatment plus the administration of sulpha drugs and penicillin will have on the incidence of mastoiditis remains to be seen.

I should like to express my thanks to all my colleagues whose cases have formed the basis of this paper, particularly Dr. William Gunn of the North-Western Hospital, and Dr. M. Alexander of the North-Eastern Hospital, whose notes and statistics I have used.

Mr. John E. G. McGibbon: In view of Miss Hall's comprehensive account of the syndrome of acute otitis media, latent mastoiditis and diarrhæa and vomiting in infants, I propose to base my remarks on observations made on a series of patients who have been under my own care during the past sixteen months.

Incidence.—The frequency of infection of the middle-ear tract in infants is still not appreciated, and until recently the most striking evidence of the prevalence of such infection came from the post-mortem room.

Ebbs' (1937) figures are frequently quoted. He stated that 368 (61%) of 603 infants who died whilst suffering from diarrhæa and vomiting were found at autopsy to be suffering from a purulent infection of the middle-ear cleft.

Coupar and McConkey (1937) found that, in 1936, of 1,324 infants under 1 year of age admitted to Alder Hey Children's Hospital, Liverpool, 195 (14%) suffered at one time or another from otitis media, or otitis media and mastoiditis, and an analysis by Derham (1947) shows that 240 (21.6%) of 1,107 infants admitted to the hospital in 1946 were suffering from aural infection when first examined, and that 191 (17.2%) developed a lesion of the middle-ear cleft after admission—making a total of 431 (39%) infants with ear disease, and in 193 (44.7%) of these cases this was associated with diarrhæa and vomiting.

Material used in the following notes.—During the sixteen months from September 1945 to December 1946, 104 infants suffering from diarrhæa and vomiting were operated on for latent mastoiditis in this hospital; and during the same period, 32 infants, who died of diarrhæa and vomiting and who were unsuspected of mastoiditis during life, were found to have a purulent infection of the tympanic cavities and mastoid antra at autopsy. I think it may be assumed that during this period there were more infants who died with unrecognized mastoiditis who did not come to post-mortem.

The following observations are based on the records of 67 of these patients operated on personally—all of whom were suffering from diarrhæa and vomiting when seen by me—and of the 32 cases found at autopsy to have suffered from undiagnosed infection of the mastoid antra, making a total of 99 cases.

The figures quoted are for comparison only and are of no statistical value.

The average age of the infants operated on was 4.3 months, and of the undiagnosed cases it was 3.6 months. Two of the undiagnosed cases were under 1 month of age.

Ætiology.—The ætiology of the syndrome is illustrated diagrammatically in fig. 1.

Diarrhæa and vomiting (1, fig. 1) may result from:

(a) *Enteral infections* (2, fig. 1), i.e. a true gastro-enteritis, which may be bacterial or caused by a virus. In the present series, rectal swabs were negative in 66.6% of the cases so examined (Table I) and the weight of evidence to-day is in favour of a virus infection (*Lancet*, 1947).

TABLE I.—BACTERIAL FINDINGS IN RECTAL SWABS OF 66 PATIENTS

	Positive (<i>B. proteus morgani</i>)	Negative	Total
Survivors	7 (31.8%)	15 (68.1%)	22
Fatalities	5 (21.7%)	18 (78.2%)	23
Undiagnosed	10 (47.6%)	11 (52.3%)	21
Totals	22 (33.3%)	44 (66.6%)	66

Pathological changes in the bowel were found in only 10 (27%) patients of 37 who were examined post mortem—i.e. only about a quarter of these cases were suffering from a true gastro-enteritis (Table II).

TABLE II.—CHANGES IN THE BOWEL FOUND AT POST-MORTEM IN 37 INFANTS

Fatalities	Positive (Distension, hyperæmia pseudo-membranous inflammation, hæmorrhage or hæmorrhagic contents)		Total
	Nil (Nil)	Negative	
Undiagnosed	10 (35.7%)	9 (100%)	9
		18 (64.3%)	28
Totals	10 (27%)	27 (73%)	37

There is evidence that in both sporadic and epidemic cases of infantile gastro-enteritis changes are found in the brain which are characteristic of an infection by a virus.

(b) *Parenteral infections* (3, fig. 1) such as otitis media, pneumonia, pyelitis, cellulitis, erysipelas, &c.

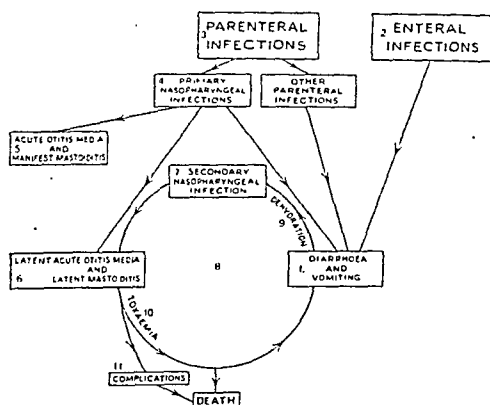

FIG. 1.—The syndrome of acute middle-ear cleft infection, mastoiditis and diarrhoea and vomiting in infants.

In 1930 Marriott wrote in the introduction to his book that: "Many of the disturbances of infants which have previously been attributed to dietary faults are in reality the results of infection" . . . and that "the most frequent infections that interfere with nutrition are otitis media and pyelitis" . . . and it is now generally recognized that vomiting and diarrhoea may occur in infants suffering from any acute infection.

Otitis media and mastoiditis.—Infection of the middle-ear cleft is usually secondary to nasopharyngitis, and it is caused either by direct entrance of organisms along the eustachian tube—some observers have stated that they have found ingested milk in the mastoid antra—or by lymphatic spread.

If blood-borne infection of the middle-ear cleft does occur in infants, the number infected in this manner must be very small.

Naso-pharyngitis may be due either to:

(a) *Primary* upper respiratory infection (4, fig. 1), which in the infant sometimes may be so slight and transitory as to escape recognition.

This may give rise to *manifest* acute otitis media and manifest mastoiditis (5, fig. 1) with swelling and redness over the mastoid process, which is an infrequent occurrence. It is a benign condition which causes little constitutional disturbance and which is cured by operation.

Or it may give rise to *latent* acute otitis media and latent mastoiditis (6, fig. 1) which will be described later.

(b) *Secondary* infections (7, fig. 1) caused by organisms deposited in the nasopharynx by vomiting and/or regurgitation.

It is obvious that vomiting can infect the nasopharynx, so that secondary nasopharyngitis may result from enteral or parenteral infections.

FIG. 2.—Diagram of special splint and towel. S.T.—special towel, 48 in. × 52 in. (See p. 11).

Fig. 1 demonstrates that none of the lesions mentioned can be regarded as a separate entity—all may be recognized as part of a syndrome—the *syndrome of acute otitis media, latent mastoiditis and diarrhœa and vomiting* which constitutes a vicious circle (8, fig. 1).

Vomiting and diarrhœa lead to dehydration (9, fig. 1), toxæmia (10, fig. 1) and other serious complications (11, fig. 1).

The vulnerability of the infantile middle-ear cleft may be explained partly by certain anatomical features whereby organisms in the nasopharynx can obtain easy access to the tympanum and antrum along the eustachian tube, or whereby drainage of the more distal portion of the cleft is impaired.

First the infant eustachian tube is shorter (14 mm.) than the adult tube (32-38 mm.); it is more horizontal, so that the level of the infant's tympanic floor is slightly below that of the floor of the nasal fossæ (in the adult it is 20-22 mm. above the hard palate), and its lumen is relatively greater than that of an adult.

Secondly the middle-ear cleft is developed from the tubo-tympanic recess which grows out from the primitive pharyngeal pouch into a mass of mesenchyme.

It is stated that in the infant tympanum there sometimes is a residue of the mesenchymal tissue in the region of the aditus which is not absorbed entirely until several months after birth; and it is possible that in some cases this residual tissue, as a result of infection, becomes swollen and blocks the aditus; this also may be one of the explanations of a dry myringotomy in some cases of latent mastoiditis.

Diagnosis.—The nomenclature of the disease from which the infants were considered to be suffering at the time of admission to hospital was dependent on the predominant symptoms present at the time, on the particular interest of the admitting Medical Officer, and on his ability to see the drumhead.

Thus, from the series of 99 infants known, or found, to be suffering from latent mastoiditis, the diseases noted on admission are shown in Table III, and it will be seen that 61 (i.e.

TABLE III.—DISEASES NOTED ON ADMISSION OF 99 INFANTS SUFFERING FROM LATENT MASTOIDITIS

61.1%) were considered to be suffering from diarrhœa and/or vomiting, and 20 (i.e. 20.2%) from otitis media, alone or in association with lesions of other organs.

If the drumhead is not normal the infant is certainly suffering from middle-ear cleft infection, and he may or may not have a latent mastoiditis.

The appearances of the drumheads on admission of 60 of the 67 cases submitted to operation were entered on the case-sheets, and, although in 39 (58.1%) infants one or both drumheads were noted to be abnormal, only on 20 (29.8%) of these case-sheets was otitis media included in the original diagnosis.

Symptoms.—Symptoms pointing to middle-ear cleft infections in infants may be few or absent.

Head-rolling, restlessness, fretfulness, screaming attacks, drowsiness and, in a few, convulsions, may be present.

Signs.—*General signs* are those of failure by infants suffering from diarrhoea and vomiting to respond to adequate general treatment.

The most urgent signs are persistent vomiting and diarrhoea with loose green stools, dehydration and loss of weight; particularly if these are associated with any considerable rise of temperature.

Local signs can be found only by otoscopic examination.

The drumhead may be lustreless, grey, crinkled, invaginated or full and congested. Occasionally sagging of the postero-superior wall of the meatus may be present.

Otorrhoea is not a frequent finding—it was noted in 6 (8.9%) of the 67 patients submitted to operation.

Latent mastoiditis should be *assumed* only if the symptoms do not improve after a dequate drainage of the tympanum has been established, either by spontaneous perforation or by incision of the drumhead.

Bacteriology and pathology.—Whether the diarrhoea and vomiting be caused by a virus or by bacterial infection, there can be no doubt that the mastoiditis is bacterial.

The organisms cultured from the mastoid antra of the 99 cases are shown in Table IV;

TABLE IV.—BACTERIOLOGICAL FINDINGS OF THE MASTOID ANTRA IN 99 CASES OF INFANTILE MASTOIDITIS

Findings unknown or not cultured	—	—	2	2

and from this it may be seen that *B. coli* alone or with other organisms were obtained in 36 cases, of which 30 died; *Staph. aureus* were found alone or with other organisms in 25 cases, of which 9 died; and pneumococci alone or with other organisms were present in 14 cases, of which 12 died.

Hæmolytic streps. were present only in 4 cases, which is a surprisingly low figure.

It is interesting to note that only in 50% of the cases similar organisms from the meatus and mastoid antra were cultured.

The organisms found by culture from the antra are shown in column A of Table V, and I have compared them in column B with the bacterial findings in 92 cases of acute suppurative otitis media, not in infants, quoted by C. P. Wilson (1946). Both of these series occurred in the same period—i.e. 1945-46, so they are strictly comparable.

TABLE V

A (McGibbon)				B (Wilson)	
Infants with gastro-enteritis (99 cases)				Non-infants (92 cases)	
<i>B. coli</i> alone or with other organisms	36 (36.3%)	Nil	
<i>Staph. aureus</i> alone or with other organisms	25 (25.3%)	19	(20.6%)
Pneumococci alone or with other organisms	14 (14.1%)	18	(19.5%)
Hæmolytic strep. alone or with other organisms	4 (4.0%)	46	(50.0%)
Others	16 (16.1%)	6	(6.5%)
Sterile	14 (14.1%)	3	(3.2%)

Of the infants submitted to posterior drainage the best results were obtained in those from whom *Staph. aureus* were obtained by culture.

The fourteen patients from whom sterile cultures were obtained had all been subjected to intensive chemotherapy and systemic penicillin, which may have been the cause of the absence of bacterial growth.

When pus was present it was usually of a thick tenacious nature.

In all cases except two, the naked-eye pathology was confined to the mucoperiosteum; and the lesions observed were congestion and/or œdema of the mucosa and the presence of serous or purulent fluid.

In two patients only was there an obvious osteitis. Sections of bone were not made and the impression gained was that the antrum was a cesspool of pus which did not kill by toxæmia but by causing a persistence of the diarrhœa and vomiting (see fig. 1).

The absence of bone disease is borne out by the investigations of Causee (1946). He sectioned seventeen mastoid bones of 13 athreptic infants with mastoiditis and found no involvement of bone by infection.

Treatment.—General treatment is a pædiatric problem, and the amount of time, effort and skill in this respect that has been spent by the Resident Medical Officers and Nursing Staff on these patients has been unbounded.

There is one point that I would stress in regard to general treatment, and that is the importance of active measures to restore the fluid content of the body by the intravenous route—in dehydrated infants this is a most valuable pre- and post-operative measure; in some cases the infusion of whole fresh blood appears to be a life-saving procedure.

Systemic penicillin and sulphonamides do not appear to have any beneficial effect.

Local treatment.—If an infant with abnormal drumheads suffering from diarrhœa and vomiting fails to respond to general treatment, myringotomy should be performed.

In very many cases this marks the turning-point to recovery.

Sometimes there may be an audible "pop" on incision of the drumhead, which Le Mee (1937) considers to be due to air rushing into the tympanum; but in the presence of gas-forming organisms it may be due to the gas rushing out.

The products of myringotomy in 61 of the 67 cases operated on were as follows:

(1) *Dry incision* in 5 cases (8.2%). A dry myringotomy may be due to (a) dehydration—such a dry middle ear will discharge when the fluid balance of the infant is restored; or, as mentioned earlier, it may be due to (b) obstruction of the aditus by swollen mesenchyme.

(2) *Blood only* in 8 cases (13.1%). This may conceal any other fluid that may be present, or

(3) *Serous fluid or pus* in 48 cases (78.7%). This was the most frequent and satisfactory finding.

Preliminary myringotomy was performed in 61 of the 67 patients operated on by posterior drainage, and in 15 of these the drumheads were incised on more than one occasion.

After reviewing the cases, I am of opinion that valuable time may be lost by repeated myringotomies, as 10 cases (66.6%) of the 15 submitted to more than one myringotomy died; and I consider that if an infant does not improve within twenty-four hours after preliminary myringotomy, the mastoid antrum should be drained by the posterior route.

Posterior drainage is a simple operation carried out under local anæsthesia, after premedication with chloral and bromide.

I do not propose to describe the operative technique in detail.

Before operation the infant is bandaged to a splint (fig. 2, p. 8) and during the operation his head is held in position by a nurse, whose hands are covered with a towel with a small hole to leave exposed the ear and mastoid region.

After operation the antrum is lightly packed, and the wound is kept open and allowed to heal by granulation.

It may be necessary to insert one or more hæmostatic sutures which are removed in twenty-four hours.

Of the 67 cases drained in this manner, in 59 both mastoid antra were opened, and in 8, one antrum only was drained.

Of the 126 mastoid antra opened, 10 were macroscopically normal, but from 7 of these positive bacterial cultures were obtained.

As the unopened antrum was found to be infected at autopsy in 2 cases, and, as infection of both antra was present in 26 of the 32 cases of unrecognized mastoiditis, it has been my practice latterly to explore both antra at operation, if both drumheads were abnormal.

Convalescence often was stormy and extended over several months.

Results of operation.—The results of operation on paper are deplorable. 36 patients (53·7%) recovered, and 31 (46·3%) died, but I am convinced that without operation the mortality rate would have been over 90%.

The majority of patients came to operation as a last resort in regard to treatment; and they were, in fact, moribund at the time of operation; and I consider that these findings demonstrate the necessity of *early* operation if a preliminary myringotomy fails to bring about improvement of the infant's condition within twenty-four hours.

My thanks are due to Dr. W. E. Crosbie, Medical Superintendent of Alder Hey Children's Hospital and to the Resident Medical Officers; also to Dr. H. Lederer for the bacteriological investigations and Dr. Joan Gregory and Dr. Eileen J. Owens who abstracted the case-sheets.

The Chairman said the idea which appealed to him personally was that in these cases there was a general infection instituted by a virus with an attempt by the individual attacked to develop a fixation abscess in the middle-ear cleft. When this attempt by Nature had succeeded, there would be a better chance of survival with help from the otologist to assist drainage.

Was it the general rule to find otitis media on both sides, rather than in one ear alone?

Mr. H. S. Sharp said that in the two years 1944-46, 492 cases of gastro-enteritis were admitted to the Hospital for Sick Children, Great Ormond Street, upon 36 of whom bilateral mastoid operations were performed. These were done following paracentesis which did not lead to resolution of the otitis media. 9 myringotomies were also performed which *did* lead to resolution of the otitis media. Of the 36 bilateral mastoids, 30 were subjected to a detailed analysis in the endeavour to discover any pointer to help in diagnosis. Of these 30 cases, following the opening of the mastoid, 16 were found to have pus in the mastoid on both sides and 14 had clear mastoids. In other words, there was an error of practically 50% in the diagnosis. These cases were also subjected to a five-day white count done according to the Schilling method. This failed completely to assist in the diagnosis. In the 16 cases which had pus in the mastoid the average white cell count was 16,000, and in the 14 cases with no pus it was 18,000. The other point was whether the influence of penicillin had had anything to do with the production of a sterile culture from the mastoid. This again gave an indeterminate result. Altogether the investigations directed to forming some diagnostic criteria had not helped at all.

Mr. James Crooks said that he had been interested in Miss Hall's remarks concerning the epidemic character of the association of otitis media with gastro-enteritis of infants. He thought that Marriott (*Ann. Otol. Rhin. Laryng.*, 1928, 37, 71) was the first person to discover this epidemic association. In 1942 and 1943, to which years Miss Hall's figures largely related, there were quite a number of cases at Great Ormond Street in which gastro-enteritis was associated with otitis media. Those seemed to be epidemic years. He had

little doubt about the respiratory infection, but he did not think there was any reason to concentrate on the ear. It was a respiratory infection that caused these troubles, and not necessarily an ear infection. It might be a pharyngitis or a sinusitis.

At Great Ormond Street they had been aware of the possible association of otitis with gastro-enteritis for many years. Every case presented problems of its own and when an aural operation was performed the indications for it were often less adequate than they would have desired. There was a class of case in which the physician declared that the child was dying and that he had done all he could, and suggested that there might be a hidden infection in the mastoids. The mastoids had sometimes been opened in such cases without any local indication at all, and pus had been found although there was nothing to indicate from the outside that it was present. Sometimes these babies seemed to have recovered as a result of this operation, which was simply an exploration.

The most usual clinical picture was that of the baby who came into the hospital with gastro-enteritis, and, often within a few days of admission, coinciding usually with an exacerbation of the diarrhoea and vomiting, the tympanic membranes were noticed to be abnormal; not the red bulging membranes of which Miss Hall had spoken, but dull drums, slightly pink and thick. Sometimes the baby improved after incision of the drum; at other times the improvement was only temporary, more vomiting and diarrhoea ensued, and then the mastoid was opened. In quite a number of these children pus was found in one mastoid or in both, and they were assured by the physicians and sisters alike that there had been immediate improvement. The cases which really troubled them were those in which they opened the mastoid and found nothing, and the baby started to get better. No one knew why—whether or not it was due to the new interest in the child—but it did happen.

He would not be prepared to say that infection alone in the ear could cause gastro-enteritis—he had seen so many babies with acute otitis media with not the slightest sign of gastro-enteritis. He had opened many acute mastoids in infants in whom there was no gastro-enteritis. He thought that mastoid infections were likely to occur in any debilitated baby that was vomiting as it lay on its back. In such a position some of the vomit passed into the short wide eustachian tubes, and he had actually seen milk in the mastoid antrum. When an infection did occur in the ear, as he had said, it made the child's gastro-enteritis worse. Sometimes they responded to incision of the ear drum, at other times to opening of the mastoid. It seemed quite certain that babies with diarrhoea and vomiting should have their ears examined daily. Any sign of inflammation in the drums called for paracentesis. He did not think the mastoid should be opened if there were no signs of inflammation in the ear. They had to go on such clinical signs as were apparent, and he would be doubtful about doing this operation just on the chance that some infection might be there.

Mr. Eric Watson-Williams said that in the last fifteen years he had seen rather less than 100 of these children. But he was quite convinced that a proportion of these had infective material in the antrum, and some of these children who seemed desperately ill certainly did recover after the infective material had been given artificial egress. Further than that he found it difficult to go. He rather supported the view that every reasonable measure that might tend to turn the scale should be undertaken. Mastoid opening in a small infant was not an operation of great severity. It was a matter literally of minutes—of very few minutes in fact—and he liked to feel that, unless the baby was over six months, he could complete the operation well inside five minutes. There ought not to be much shock.

He had been particularly interested in Miss Hall's remarks on periodicity. Periodicity in diseases was a most fascinating subject. He had analysed the periodicity of pneumococcal infections in the sinuses, and it was most extraordinary how waves of pneumococcal sinusitis in children were seen. For three or four years there would be very little, and then suddenly there would be a great deal. It was probably perfectly true that the virus turned up in waves (*Brit. med. J.*, 1929 (i), 720).

Mr. W. Stirk Adams said that Miss Hall had quoted figures which led one to hope that the medical treatment of the entity which they used to know, and still knew, as diarrhoea and vomiting was so improved that the mortality had been reduced from 30% of all cases as it was years ago to 9% last year. Whether that was because they had admitted to the hospital larger numbers of children in a less severe degree of illness they had not been told, but a study of the paper would be very useful to them all, and his comments at the moment must be tentative.

Mr. McGibbon appeared to have been dealing with a more severe type of case; and he had found otitis much oftener than Miss Hall. This difference was interesting and might be

It may be necessary to insert one or more hæmostatic sutures which are removed in twenty-four hours.

Of the 67 cases drained in this manner, in 59 both mastoid antra were opened, and in 8, one antrum only was drained.

The Peep-Show Technique for Pure Tone Audiometry in Young Children¹

DEMONSTRATION AND FILM

By M. R. DIX, F.R.C.S., and C. S. HALLPIKE, F.R.C.P., F.R.C.S.

(*Otological Research Unit, Medical Research Council, National Hospital, Queen Square, London, W.C.1*)

Mr. Hallpike said that the test procedure to be described had been designed to solve the difficult clinical problem of the young child, under the age of 5 years, in whom backwardness was associated with failure of speech development. The failure might be due to deafness, to mental defect, or to a purely motor disorder of speech. The otologist was called upon for an authoritative opinion on the hearing, and here the question of a suitable test was a very difficult one. Ordinary speech tests were very difficult in the presence of deafness with defective vocabulary, while young children found pure tone audiometry very boring, and their responses were in consequence unreliable. A still greater difficulty attended the standard test procedure for pure tone audiometry; namely that before the test could be applied the child needed to be given and to assimilate an explanation of the nature of listening and hearing with the telephone receiver. This was often impossible. In designing the Peep-Show procedure they had endeavoured to overcome these difficulties: First, by giving an arresting significance in the child's consciousness to the usually uninteresting pure tone stimuli; secondly, by so devising the test that the child was persuaded to respond to the sound stimulus with no explanation other than a very simple dumb show.

Mr. Hallpike then demonstrated the test equipment and showed a short film of deaf children undergoing the test. He said that the method was of particular value between the ages of 3 and 6 years. With children of normal intelligence decisive results were nearly always obtained in the course of a single visit to the Clinic.

Miss Dix said that a vital point in the management of the children was that they should not be seen when tired or hungry. All cases were seen by appointment in a quiet room with their parents. It was essential not to attempt this in a busy Out-Patient Department. During the interview she played with the child while Mr. Hallpike talked to the parents while observing the child and assessing its intelligence. Only when its co-operation had been secured in this way did they proceed to the Peep-Show test.

Mr. Terence Cawthorne said that he had the advantage of having seen this device in action and of providing Mr. Hallpike with some deaf children to test. One of the most difficult problems in otology was a child under 5 who, though obviously hard of hearing for speech, was able to hear certain sounds. It was important, in such cases, to make a reasonably accurate estimate of the child's hearing. It might be labelled as requiring psychological treatment, or for education at a deaf school, when in fact it could quite well be educated with appropriate assistance with hearing children. Therefore any method of testing that gave a better and more accurate picture of the hearing capacity was of the greatest importance. Some of these children were very shy and would not respond to any form of sound at all, and yet one felt that there was some hearing. With the peep-show technique such children could be made to respond when all other methods failed.

¹For a full description of the test procedure and equipment reference should be made to the authors' article in the *British Medical Journal*, 1947 (ii), 719.

due to the conditions under which Mr. McGibbon worked and might correspond to the practice as they saw it in the Children's Hospital at Birmingham, where the physicians and pædiatricians were in charge of their patients, where there was a constant watch on the drumhead, and where they did their best for the patient, but called in the otologist to carry out the necessary treatment the moment there was any doubt about the ear.

The most important point was the time of intervention. It was highly disadvantageous to open the mastoid too early or too late—if too late there was secondary general infection and the case was hopeless.

Mr. G. A. Fraser said that they had had a rather severe outbreak of infantile gastro-enteritis in the Brighton area recently, and Mr. Allen and himself had had a very worrying time deciding upon which children they should do a mastoidectomy. During the last year 27 bilateral mastoidectomies were performed on babies suffering from gastro-enteritis. In half of these cases there were signs of middle-ear disease, but the other half showed no clinical signs of middle-ear or mastoid infection, and these cases were operated on only after a great deal of pressure from the physicians. The striking thing was that of the 27 cases operated upon only two were found to have perfectly healthy mastoid processes.

Miss Winifred Hall, in reply, said that most of her cases had been in the L.C.C. fever hospitals, where the majority of London gastro-enteritis cases were now sent, in preference to the general hospitals. Although a certain number of mild cases were sent in, the majority were very acutely ill, and while she could not give figures, it was quite certain that the fall in the death-rate was due to improved treatment, and not to a greater number of mild cases. She was strongly of opinion that the mortality of the disease had a great deal to do with the pædiatric treatment, and the greater the experience and care of the pædiatrician and nursing staff, the better were the results. In one hospital showing very good results the medical officer in charge of the wards had been dealing with nothing but gastro-enteritis for the last four years.

Mr. Crooks' point about the immediate and surprising improvement sometimes seen in babies with negative operation findings was important; she had seen it several times. Yet, in other apparently similar cases, there would be no improvement, and the child would die. She did not know any reason for this improvement. She had not found any laboratory procedures of help in making a diagnosis; she went on the lines given in the paper. Also when one had seen a number of these cases, one acquired a sixth sense about them which was quite as helpful as any sign. The white cell count was notoriously misleading. She did not know why in some cases of purulent mastoiditis an operation swab should be negative. It was not always due either to penicillin or to sulphonamides. It could occur in cases which had had neither. She had tried sending pieces of bone for culture, but even these were sometimes negative.

She did not use any form of splint at operation, merely wrapping the babies in a small blanket in the fever hospital method for tracheotomy. She had seen two cases of brachial palsy, fortunately only temporary, after the use of a splint, and was rather afraid of them. She thought myringotomy preferable to puncturing the membrane with Gray's needle. The incision healed very satisfactorily, often in twenty-four hours, and even after obtaining pus, so that there was apparently no reason to fear its remaining as a future source of infection.

As regards periodicity, at the moment in London they seemed to be at the bottom of the swing, but it might at any time come up again, and there were signs that it was now starting to do so (December 1947). She was against exploratory puncture of the mastoid antrum, on the grounds that this would not relieve extensive disease which would need further opening, but chiefly because it would miss pus confined to one or other of the groups of cells, and so mislead the operator. She had had several cases where the zygomatic cells only contained pus, and an antral puncture would not have touched them. One of the two cases that needed reopening showed zygomatic infection, and when this was cleared out, the child promptly recovered.

Mr. J. E. G. McGibbon, also in reply, said that in his hospital where there was a number of experienced medical officers, it was often difficult for them to arrive at an opinion as to the presence of mastoiditis on the appearance of the drumhead. Sometimes there was too much delay in calling upon an otologist to see the case, and he had heard of an infant who had four myringotomies in a period of about fifteen days. He felt very strongly that the babies who did not improve after myringotomy went down so quickly that they might be dead within forty-eight hours. The majority of the babies he saw were those in whom a myringotomy had not stopped their downward course. He thought that in such cases the mastoids should be opened within twenty-four hours and not left for forty-eight or seventy-two hours, by which time the baby might be dead.

[October 17, 1947]

DISCUSSION ON POST-OPERATIVE THROMBOSIS

Dr. Helen Payling Wright: The problem of venous thrombosis is a very serious one for the surgeon and midwife. It has been estimated that pulmonary embolism follows roughly 1:100 of all major surgical operations and that about one out of every six is fatal. The incidence of thrombosis is almost twice as common in females as in males and is most frequent after operations in which the abdominal cavity is opened and the pelvic viscera explored. It may, therefore, be of value to review the changes which occur in the blood in the days immediately following surgical operations, bearing in mind, also, that exactly similar changes occur after parturition, though in these cases the trauma is caused by excess pressure and bruising of the pelvic tissues and not by their section.

The main chemical changes which occur during the post-operative period are a rise in fibrinogen content of the plasma and an increased activity of the prothrombin. The former substance was recently shown by certain Italian investigators to undergo a diminution in concentration immediately after operation and subsequently to increase by the third or fourth day to nearly double the pre-operative value. This raised level is maintained for several days but figures are not available for more than the first seven when the concentration is still well above normal.

During the same post-operative period the activity of the prothrombin in the plasma is also enhanced. Shapero and his colleagues in 1942 followed the prothrombin levels daily in a series of cases following surgical operations, and demonstrated that the activity, after a preliminary decrease in the first few days, became markedly increased and reached a maximum about the tenth day. These findings led him to believe that hyperthrombinæmia may be used as a premonitory sign in thrombo-embolism. The desire to be able to foretell the onset of thrombosis is, naturally, very great and recently Mayes has suggested that the presence of a form of fibrinogen, fibrinogen B, which has been described by Lyons in Australia, if taken in conjunction with the prothrombin times and the patient's daily temperature, will give a reliable method of prognostication. Fibrinogen B is an intermediate substance produced in the conversion of fibrinogen into fibrin. Thrombin can be shown to consist of two components, neither of which will, alone, convert fibrinogen into fibrin. The thrombin component A reacts with fibrinogen to form the intermediate product fibrinogen B, which normally passes rapidly into the fibrin form. Mayes suggests that in the pre-thrombotic state the fibrinogen B fraction, which can very easily be demonstrated by the addition of a solution of naphthaquinone to citrate plasma, is greatly increased, and that this increase is pathognomonic of incipient thrombosis. While I am sure that the method of testing for the fibrinogen B is satisfactory, I am less convinced that the interpretation put upon its presence in the post-operative patient is correct. In repeating this work recently I have carried out the test every four days in patients following operation and delivery and in all the cases under observation have found that the fibrinogen B content of the plasma is increased. This rise is usually first apparent on the fifth to seventh day and is invariably recognized by the tenth day. Simultaneous prothrombin estimations on the same blood samples showed an increased activity even in the absence of any clinical or demonstrable thrombosis. It seems likely, therefore, that these chemical changes in the blood invariably occur in the post-traumatic period and give little indication of the likelihood of the onset of thrombosis. Finally, if the fibrinogen B and the prothrombin are neither true guides to the onset of thrombosis we are left with the third only of Mayes' criteria of prognostication—the temperature—and it is well known how easily urinary infections, chest complications and even lactation can cause sudden and unexpected rises in temperature. It seems that at present it is not possible to use such biochemical changes in the blood to predict with any degree of certainty the onset of thrombosis, and the only safe course is to rely upon careful clinical observation of the patient in the post-operative and puerperal periods.

But the chemical changes are not the only ones which occur in the blood at this time. The importance of the blood platelets has long been known and the part that they play in the initiation of thrombi in injured blood-vessels by their deposition over the traumatized area is well recognized. It was not until 1928, however, that Howell Evans and his colleagues in Liverpool showed that the blood contained a greatly increased number of these elements in patients after operations and parturition. They found that the increase in numbers might be as great as 100% or more and that it usually became apparent on the

He also wished to emphasize that the diagnosis of deafness in young children should remain within the province of the otologist. If he employed a technician to assist him the relationship should be the same as between radiologist and radiographer. They all knew that the best conducted radiological departments were those in which the radiographer was under constant supervision by the radiologist. In a highly critical technical procedure such as the Peep-Show it was of paramount importance that the work should be under the supervision of an experienced otologist.

Mr. C. Hamblen-Thomas said that this was a most useful piece of apparatus for the clinic. He wished they could get social workers at the clinics to assist in carrying out these tests and also in undertaking the follow-up of the children. It would be interesting to learn from Mr. Hallpike whether the hearing which remained showed signs of developing under training—whether the children's perception improved to any extent.

He added that some audiometricians were being trained at the Metropolitan Throat Hospital, but their future depended on the possibility of their employment. It was of no use training girls if there was no future for them. He agreed that the otologist must be in charge initially and primarily, but if there were trained girls available they would be of great help to the otologist.

Mr. Ian G. Robin said that he himself had not had such success with children under 5, but he thought the present instrument was most suitable for children between $3\frac{1}{2}$ and 5, and not suitable for most children of between 2 and 3. Here the Ewing technique played a very important part. He thought that the Peep-Show and the Ewing technique should have a place in all deafness clinics.

Mr. M. L. Formby said that it would be a great mistake for them to feel that this was something which could be tacked on as an adjunct to a busy ear, nose and throat department and left to technicians to carry out.

Mr. Hallpike agreed that it would be quite useless to have this kind of apparatus in a busy out-patient room, and to bring the child into such a place where other things were going on probably more interesting than the test. It was necessary to use the apparatus in a quiet room where there was nothing to distract the child's attention. Another practical point was that according to the terms of the Education Act of 1944 these children now become the responsibility of the Minister of Education *before* the age of 5. Therefore the diagnosis of deafness before the age of 5 was, for administrative reasons, more important than before. He agreed with Mr. Robin concerning the desirability of getting evidence of deafness before the age of 2. The Peep-Show was not suitable for this but it was, he thought, much the most effective means of obtaining a pure tone audiogram under the age of 6 years and such an audiogram did enable them better than anything else to meet the needs of Medical Officers of Health and others who demanded a clear-cut definition of the extent of the child's deafness.

Concerning finally the necessity for training technicians to assist otologists in these tests, Mr. Hallpike said that the technical procedure was designed to be fundamentally simple and capable of being understood and supervised by otologists everywhere. With that proviso it was not really necessary to create another branch of technical auxiliaries, because any intelligent assistant could do what was required.

dissected out, giving an accurate picture of the shape of the femoral vein as it passes over the pelvic brim. Casts were taken from a series of cases and in all instances the veins showed a marked antero-posterior flattening as they passed into the pelvis. This flattening is caused by the vein lying almost directly on the bone as it passes from the leg to reach the posterior wall of the pelvis, and is unrelated to the overlying femoral ligament. The effect is best likened to the kinking of a piece of rubber tubing drawn over the edge of a table. The average of 16 pairs of vein casts shows that the actual cross-sectional area of the vein at the mid-point of the bone of the pelvic brim is smaller than in the unflattened part 5 cm. above or 5 cm. below this point. The measurements are of the order of 28 sq. mm. at the point of maximal flattening against 36 and 39 sq. mm. at points 5 cm. below and above this point. It seems likely, therefore, both that an area of weakness occurs in any clot propagated beyond this point and that some degree of stagnation must occur below the constriction at the pelvic brim. The slowing of the blood and the nipping of the clot at this point may well play a part in the formation of small emboli which break from the unattached surface of the thrombus and may be the site of origin of repeated emboli of non-fatal nature in cases of femoral thrombosis.

The making of the venous casts brought to light a further feature in femoral anatomy which is of interest to obstetricians and gynecologists.

Vein casts taken from bodies in the supine position show that there is little distortion of the vessel except for the flattening, whereas those obtained after the legs had been flexed to correspond with "Fowler's position" were bent almost to a right angle at the pelvic brim. This additional distortion is caused by the vein being bound down firmly in the femoral triangle by fascia, and must cause some further obstruction to the free flow of blood at this point and below it. The stagnation so produced must facilitate the propagation of any thrombus forming in peripheral veins of the leg. The further elucidation of the problems of stagnation in the legs of patients confined to bed is an aspect of the study of thrombosis with which I am now concerned. You will have noticed that fig. 1 included a curve of the retardation of circulation time as measured from the leg to the carotid sinus in patients confined to bed. This slowing was progressively noticeable for the first eight or nine days when it became almost steady at the reduced velocity. These figures are not, however, altogether satisfactory, first because they do not continue after the 13th day of rest, and secondly because they are not a direct measurement of the time required for the blood to pass up the leg. Leg-carotid time includes the time the blood takes to pass through the venous side of the greater circulation, the whole of the lesser circulation and finally the arterial time from the left ventricle to the carotid sinus. It is assumed that the slowing recorded in these observations is dependent upon stagnation in the legs, since arm-carotid time shows no such change, but there is no proof that this is so and that the hold-up is not in some other part of the circulation. My colleagues and I are, therefore, attempting to measure the leg venous times directly by the use of the radio-active isotope of sodium, sodium₂₄. This is injected in the form of saline in the dorsal vein of the foot and the gamma emanations given off are recorded by a shielded Geiger counter placed over the femoral vein in the groin. The method appears to be satisfactory though at present we have made too few observations to be able to say either what the normal venous time is, or yet to assess the difficulties with which we may be faced. In one subject, however, we obtained an excellent example of the value of foot movement as a pumping mechanism to move stagnating blood along the veins of the leg. Na₂₄ was injected into the foot in a subject known to have severe varicose veins. By the end of a minute no radio-active sodium had reached the counter over the groin. At that moment the subject flexed his foot dorsally a little and within two seconds a shower of gamma rays were recorded at the femoral vein. It was evident that the blood had been held up in the dilated vessels of the leg and that the slight movement was sufficient to massage it along at a much increased rate. I am sure that the importance of supervised and graded exercises and early ambulation cannot be over-emphasized in prevention of thrombus formation in the post-operative and post-parturient patient and that these are the only satisfactory methods of overcoming the stagnation factor in the formation of post-operative thrombosis.

fifth or sixth days, reaching a maximum about the tenth day and thereafter subsided to reach normality by the end of the third week. They also noted that the degree of increase in the platelet count was correlated with the severity of the operation, the more extensive the tissue damage, the greater the platelet response. In 1942, I was able to show that a further change in the platelets occurred concurrently with the increase in their numbers, namely that these blood elements become more adhesive. Observations made both on man after operations and delivery, and on experimental animals, proved that the increase in the stickiness of the platelets is maximal on about the tenth day and it appears that the new young cells which have entered the circulation in response to the stimulus of the trauma are responsible for this change in the adhesive properties of the platelets.

The correlation in time of both the chemical and the cytological changes of the blood, together with the incidence of thrombosis, are shown in fig. 1.

FIG. 1.—Incidence of venous thrombosis, blood changes and circulation times occurring in the post-operative period.

Here, too, is an incomplete curve (C) showing the changes in leg circulation times in a patient confined to bed, a factor in thrombosis about which I wish to speak presently. The closely parallel courses followed by these curves and their relation to the curve for the incidence of clinical thrombosis suggest that all the reactions are brought about by some common stimulus. In an attempt to elucidate what part of the surgical operation called forth the response, I performed some graded animal experiments in which rabbits underwent successive operations of increasing severity, from hæmorrhage and simple skin incision to splenectomy, and these observations confirmed that the extent of the rise in the platelet count is dependent upon the amount of damage to the tissues. It seems likely, therefore, that the stimulus to the bone-marrow results from the absorption of the products of tissue autolysis. This is further supported by the finding that a rise in the platelet count occurs after tissue damage other than that caused by cutting, and that the injection of necrotizing materials such as sterile silica dust or the exposure of the body to ultraviolet light are both followed by changes in the platelets similar to those occurring in surgical patients. Similarly, when tissue extracts or their products and especially the derivatives of nucleic acid are injected into animals, a platelet response is observed which corresponds to that in surgical cases.

I shall now pass to more mechanical aspects of venous circulation. The importance of venous stasis was first stressed by Virchow almost a century ago and he also pointed out that eddies in the regions of venous valves, side branches and alterations of calibre of the vessels might play a part in the development and propagation of intravenous clots. These views are still widely held, and though it is now recognized that the thrombotic process usually starts in the small plantar and calf veins, and not in the femoral vein itself, yet it is possible that the spread of the clot into the venous trunks may well be influenced by the physical features present in the large veins. Formerly anatomists believed that Poupart's ligament played an important part in thrombosis by causing a constriction of the veins at the level of the pelvic brim. But the ligament seems to me to be too lax and too anterior to exert any pressure upon the vein at this place. To test this, I tried running a plaster-of-Paris mixture, which maintained its size unaltered on setting, into the veins of cadavers, from the mid-thigh region to the common iliac. The vein was first carefully washed out with saline and the plaster was then introduced at about normal venous pressure. When it was flowing freely from the lower to the upper cannula, both ends were clamped simultaneously so that the pressure in the vein was maintained. After the plaster had set thoroughly, the cast was

FIG. 1.—Graphic comparison of total death-rate per 1,000 operations and post-abdominal pulmonary embolism death-rate per 1,000, the latter grouped by four-year periods.

Dr. Magnus Haines: *Pathology of post-operative thrombosis.*—It is intended to confine these remarks to the morbid anatomy of non-septic thrombosis. Thrombosis, when recognized, causes the surgeon anxiety on two scores, (1) the patient's convalescence must be prolonged, and (2) the patient may die as a result of dislodgment of a thrombus or a portion of it. It is commonly recognized that the sites for thrombosis are the pelvic veins, the common, superficial and deep femoral veins. During the past decade interest has been revived in following the dissection of the leg veins to *below* the knee. The results have been (1) that in post-operative cases the oldest part of the clot has been found in the veins of the deep calf muscles, and in the popliteal, and (2) thrombosis in the same location has been noted in up to 25–50% of patients, mostly over 40 years of age, who died of a variety of conditions of no surgical interest, but who had been bedridden by their illness. These investigations have not, however, helped in any way to establish an answer to the question "how soon after an operation may thrombosis occur?" But at the same time it is obvious that thrombosis may be present even before operation in patients who have been in bed some time. A more detailed account has been given by Short.

Clinically it is important to remember that (1) Thrombosis is often symptomless and without physical signs. (2) Time of onset is variable, not "ten to twenty-one days after the operation". (3) Most of the patients are over 40 years.

Convalescence may be prolonged because of the thrombosis or because of embolism. It is held by some that nearly all fatal embolisms occur in cases of unsuspected thrombosis. Embolism commonly occurs in one of two clinical forms, the second sometimes following the first. In the first we have embolism, usually pulmonary, leading to small infarcts. Pulmonary infarction has a characteristic clinical picture, but I would stress that it may be silent in onset or the symptoms and signs, often atypical, may be misinterpreted, e.g. as pneumonia, basal collapse, paroxysmal tachycardia. The mechanism by which the thrombus becomes separated is not yet clear. In some cases, small pieces of the proximal end become emboli while in others the embolus is 45 to 55 cm. long. Undue friability of the clot may account for its fragmentation. It is probable that the "long embolus" results from some agent which breaks down the clot's anchorage to the endothelium. It is finally separated by intravascular friction associated with increased blood flow.

I do not propose to deal with the prevention of thrombosis or its treatment. There can be little doubt that solutions of the many problems will be found, as indicated by Short (1947, *Proc. R. Soc. Med.*, 40, 195), in changes taking place in the plasma, and in the corpuscular elements of the blood, particularly platelets. Here I would call for a much more careful record-keeping by our clinical colleagues, with publications, of the incidence of post-operative thrombosis and non-fatal embolisms. As pathologists we have no difficulty about recording the fatal cases.

In order to gain some idea of the incidence of fatal pulmonary embolism we have reviewed the operations performed at Chelsea Hospital for Women from 1927 to 1946 inclusive. There were 55 cases of fatal pulmonary embolism in over 30,000 operations performed. Abdominal operations numbered 11,748 with 43 fatal pulmonary embolisms. "All other operations" showed 12 fatal embolisms. The twenty years can be divided equally and it is found that just over 15,000 operations were done in each period. Furthermore, a new regime of physiotherapy was operating during the second ten years. At first sight, the figures indicated gratifying results in the latter group. But it became apparent that other factors required consideration.

Thus from Table I it is seen that the total deaths per 1,000 operations have fallen steadily, on the average, during the whole twenty-year period, although they clearly cannot continue to fall at the same rate. If Y is the death-rate per 1,000 and X is the year, coded so that 1927 = 1, 1928 = 2... 1946 = 20:

$$Y = 18.08 - 0.753 X \dots \text{approx.}$$

This line is a very good fit to the data (*see* fig. 1), its slope is more than 10 times the standard error and is thus highly significant statistically. The departures of the observed death-rates from this line are no more than is to be expected by chance ($\chi^2_{[15]} = 11.69$, $P = 0.80$ to 0.90) and a curve does not fit the data significantly better than this straight line.

On the other hand deaths due to pulmonary embolism are not so clearly dependent on time as are the total deaths. During the first ten years there is no indication of a changing death-rate. Such changes as occur in the second ten years relate only to abdominal operations. In order to examine the likelihood that the abdominal pulmonary embolism fatality rate during the second ten-year period differed from that during the first, a χ^2 test was made, grouping the data so as to obtain expected numbers of not less than about 5 on the hypothesis that a uniform death-rate of 3.660 per 1,000 held throughout the twenty years. On this hypothesis, the expected and actual deaths are shown in Table II.

(1) Pulmonary embolism.—The majority of first pulmonary embolisms are small ones and frequently are diagnosed as pleurisy and put down to post-operative chill from sweating, cold corridors and so on; the one small tell-tale disc of blood-stained sputum produced twenty-four or forty-eight hours after the pain is not noticed, or if noticed, not reported. It would be safe to generalize and state that every case of stitch-like pain in the ribs after an operation is an embolism and, furthermore, a warning of others to come and a 30% chance of fatality. A second important generalization is that the embolism originates in the posterior tibial veins, and even if not clinically evident, the ligation of both superficial femoral veins should be carried out at once; this done one need have no further anxiety on the score of embolism. Heparin and dicoumarol therapy is also employed after the ligatures to make assurance doubly sure. It often happens that after a bilateral ligation the affected leg, not apparent clinically, generally the left, will disclose itself by swelling up while the other shows no change of any kind; the amount of this swelling is greatly reduced by anticoagulant therapy possibly combined with lumbar ganglionic block.

(2) Thrombosis of varicose veins after operation is very worrying. These veins themselves never manufacture emboli, but the thrombus may extend to the saphenous or popliteal opening and involve the deep veins, or—more important—the post-tibial veins may also share in the general insidious tendency to clot and do so, as they often do, without producing any clinical signs. On the whole I think it safest to ligate the common femoral veins above the saphenous openings in these cases.

(3) Thrombosis of normal superficial veins either spontaneously or following venoclysis. In these cases the legs should both be carefully examined for deep thrombosis, and if this is the only lesion ligation of the common femoral vein should be done on the same side above the saphenous opening. It is best to avoid the leg veins entirely for venoclysis and only resort to them in dire necessity when the arm veins are exhausted.

(4) Phlebothrombosis of the posterior tibial veins is a very insidious condition and is frequently missed. The pain is not great and is not reported by the patient who thinks it is a "muscular strain", and frequently there is no pain at all. The condition will only be discovered by routine examination of the lower calves for tenderness and pain in the same region on dorsiflexion of the foot (Homans' sign). The condition sometimes produces a steadily rising pulse-rate (Mahler's sign) and a mild pyrexia. Once discovered the condition must be regarded as urgent and dangerous and ligation of the superficial femoral vein made at its junction with the deep vein on the affected side. The usual anticoagulant therapy follows the operation.

(5) Massive femoral thrombosis thrusts itself on the attention, but it cannot be too strongly stressed that it is often preceded by the less obvious conditions above (1, 2, 3 and 4) and if steps had been taken in time, this final dénouement would not arrive and much trouble avoided for all. Phlegmasia alba dolens in full flower is an awesome sight. The leg, soapy-white or cadaveric blue, ice-cold from sweat and blown up as tight as a football, produces great systemic disturbance if development is rapid by the great abstraction of fluid from the rest of the body. When both legs are inflated simultaneously the abstraction of fluid may be so great as to produce a fatal outcome. On two occasions I have been able by administration of intravenous saline to snatch a moribund patient from the grave; in one case the collapse was thought to be due to pulmonary embolus and in the other to a cardiac infarct. A litre of intravenous normal saline was enough to make the diagnosis clear. In phlegmasia alba dolens it was customary in other days to stand helplessly by, give morphia to the immobilized patient and watch the condition progress, frequently spread to the other leg and finally slowly defervesce; after six to twenty-four weeks of extra bed the patient would get up crippled for life. Thanks to the genius of Leriche this is no more; he pointed out that the leg was cold and icy and it was easy to alter that, and that done, other benefits might accrue. The lumbar ganglia are injected with novocain immediately the condition is manifest, the leg warms, arterial and venous spasms disappear, the blood flows freely, the vicious circle is ended and the swelling starts to go down; no more morphia is needed and generally within a week the patient, with appropriate support for the leg, is out of bed. Most important of all, the permanent damage is lessened, and we can hope that twelve years later there will be a reduction if not an absence of the hitherto inevitable pigmentation, ulceration, eczema, callous œdema and recurrent phlebitis which we see at present.

For many years tentative efforts in which I have joined from time to time have been made to extract the clots from the femoral veins so as to diminish the permanent effects. Phlebography as practised by Dos Santos promises to put this on a more rational basis, and the extent of the clot can be accurately defined and a suitable operation planned with good prospects of success.

(6) Iliac thrombosis is of special interest to the gynæcological surgeon. There is no doubt that the iliac vein close to the operation area is the initial starting-point in certain cases of femoral thrombosis but in only relatively few cases. The more usual thing is for it to start

Thus, there is a statistically significant difference between the fatality rates for the two ten-year periods, but no evidence of further discrepancy. The chance is approximately 40 to 1 that the death-rate fell in the second ten-year period as compared with the first, and the best estimate of this fall is from 4.72 per 1,000 operations to 2.22 per 1,000. It should be noted that this is very much the same as the general fall in all deaths of from 14.1 per 1,000 in the first period to 6.0 per 1,000 in the second.

It is hoped that when the next ten-year survey is reported, a still greater reduction in fatality rate will have been achieved as the result of efficient use of anticoagulants.

Mr. A. Dickson Wright: Post-operative complications have one by one been circumvented by improvements in the performance of the operation and the administration of the anæsthetic combined with more rational treatment before and after the operation. In addition, these complications themselves, if they should develop in spite of all precautions, can be treated much better with modern agents. The occurrence of venous clotting after operations and childbirth is an accepted fact although some are inclined to minimize it and say that it never occurs in their personal practices. This attitude is not correct or fair to patients, the condition is prevalent enough to be taken seriously, it is dangerous to life and will, if recovered from, leave disabilities and miseries for the rest of the patient's lifetime. There is a certain reluctance to take precautions against the condition because it is said to be so rare, and when the condition has developed in spite of its rarity, precautions are not taken against embolism because that in its turn is stated to be rare also, and finally all the resources of treatment are not employed to ameliorate the condition. The sequelæ are remote, frequently not developing seriously till twelve years later, and their inevitability is not realized by all. A greater feeling of responsibility to prevent post-operative thrombosis should be evident, and when unfortunately it does occur, embolism must be prevented and everything possible done to reduce the severity of the local condition so as to leave the patient with as little crippling as possible.

Earlier speakers have stressed the post-operative blood changes which conduce to intra-venous clottings and to these I would like to add one more, viz. the increased sedimentation of the blood cells which leads to more concentrated blood and increased blood viscosity in the lower parts of the body, especially if the patient is sitting in bed.

Apart from the hæmatological factors there are certain mechanical factors which play a part. The Fowler's position causes venous stagnation in the legs and pelvis and should be abandoned; it has been now shown to be of little advantage in peritonitis for which it was invented, and it could safely be allowed to slip into the limbo of the past except in very special circumstances. Patients like to sit up in the daytime, but they should get down at night and for their afternoon siesta and be encouraged in every way to sleep upon the side. Early ambulation is becoming rapidly accepted, and expected and enjoyed by the public and the nursing profession (the bed-pan may become soon a museum piece). Early ambulation is not possible with catgut suturing of the abdominal parietes and interrupted silk stitches or a continuous steel wire stitch will have to be used. This means that operations will take a little longer but the patients will get well quicker. In addition the operation itself should be gently done and blood must not be shed needlessly, because the less the trauma and the less the blood loss the less the thrombosis incidence. Starvation before or after the operation must be reduced to the minimum, and purgation should be restrained. It is a bad custom to put the patient to bed for several days before operation. This is sometimes done to get the patient relaxed and accustomed to his new surroundings or more often to suit the surgeon's convenience or operating days. A very dangerous type of case is the one handed over by the physician after a long sojourn in bed for medical treatment which, when it fails, leads to operation. With early ambulation, bed exercises have lost their importance, but if the patient does not get up the day after the operation, then he should do some deep breathing and muscle twitching before he does.

There is one type of case requiring special consideration and that is the thrombophilic individual with a long history of thrombosis on the slightest provocation who now has to face unavoidable operation. Such patients must never have pyelographies, cholecystographies or anæsthetics by the intravenous route. At the time of operation it is well to tie the superficial femoral veins and for three weeks or even longer after the operation to keep the patients under heparin and dicoumarol therapy. A bad family history of thrombosis or embolism would also justify these measures, as would splenectomy with its bad record for thrombosis and embolism. If a fatal embolism occurs in such a case, with all concerned fully aware of the danger, it will soon be hard to exculpate the surgeon in the present state of knowledge if he has not taken the precautions mentioned.

After operation there are many different manifestations of thrombosis, and it is essential to be on the look-out for them so that prompt measures can be taken. The various situations which may confront the surgeon are as follows:

for post-operative cases. Admittedly, some surgeons get their patients up very early, but the patients do not like it. My practice is still rather conservative, both obstetric and gynaecological patients not being allowed up until the tenth day, or later.

With reference to the value of graduated post-operative exercises conducted under the direction of the ward sister and sometimes to the accompaniment of music, I should like to quote the very striking summary of Sir William Fletcher Shaw's article in the *Journal of Obstetrics and Gynaecology of the British Empire*, 45, No. 3, 451. "In two institutions in wards under the care of the same gynaecologist, admitting the same type of patient, with the same pre-operative and post-operative treatment—except that in one systematic graduated post-operative exercises were given and not in the other—this gynaecologist performed 1,635 consecutive operations in the hospital with graduated exercises with an incidence of fatal pulmonary embolism of 0.06%." In the other hospital without graduated exercises the same gynaecologist performed 3,618 operations with an incidence of fatal pulmonary embolism of 0.304%, a percentage incidence five times as great as in the other group.

To turn now to some of the more modern treatments. It is well recognized that even cases of sudden and severe pulmonary embolus can now be saved by using large doses of heparin immediately. It is probable that we have been using far too small a dose in this country. We have been using such quantities as 5,000 units, in reality this is only 50 mg. and quite inadequate.

There is confusion nowadays because the dose may be referred to as milligrams or units. All that need be remembered is that 1 mg. of pure Toronto heparin corresponds to 100 units. Now, the usual preparation available is Liquemin Roche, which is put up in 5 c.c. ampoules, containing a total of 50 mg. To give a dose adequate for a case of pulmonary embolus would thus mean giving 2½ ampoules (125 mg. 12,500 units) immediately and 2 ampoules at five-hourly intervals. To avoid waking a patient it is wise to make the last dose at night 2½ ampoules, i.e. 125 mg.

The net cost to a hospital of one ampoule is 8s. 4d. The cost of 1 dose therefore averages about £1 and the daily cost in the region of £5 to a hospital. We private practitioners would pay much more. The concentrated solution which used to contain 5,000 units per c.c. unfortunately appears to be unobtainable at the moment. In any event, the cost of the treatment will be about the same, for 1 ampoule of this concentrated solution used to cost £2 net to hospitals. Heparin is always given intravenously and intermittent injections seem preferable to continuous dilute transfusion. It is merely a matter of drawing the contents of 2 or 2½ Liquemin ampoules into a 20 c.c. syringe and injecting it slowly, intravenously.

Temparin is another available and cheaper anticoagulant but it has a time-lag of forty-eight hours or thereabouts. So heparin *must* be given for the first two days. At the same time, temparin is started and it can be expected to take over anticoagulant duties in about two days' time. The initial dose should be 300 mg. 200 mg. is given on the second and third days. No more temparin is given until the prothrombin time is estimated. This is usually done on the fifth day and if a correct increase has taken place, maintenance doses of approximately 100 mg. daily are given. Temparin is always given by the mouth. No advantage is gained by giving it intravenously or intramuscularly. But its effect must be checked by repeated estimations of the prothrombin time. It is most remarkable to observe the differences of response to temparin in different patients.

The exact mode of action of heparin appears to be unknown. The action of temparin has been aptly described as that of a toxic narcotic to the liver cells. It thus prevents the formation of prothrombin. In estimating the prothrombin time several methods are used and it is necessary that the report should show the normal finding and the finding in the tested blood. It is desired to rather more than double the prothrombin time. If 25 be said to be the normal, one would want to find a figure of 55 to 60. If this is achieved the blood prothrombin is down by about 80%.

Embolectomy and pulmonary embolectomy are heroic surgical adventures!

Ligature of the femoral vein on both sides following the discovery of thrombosis in the veins of one or both calves seems to me just a wild piece of blood-and-iron surgery. Admittedly the ligation is done distal to the profunda femoris but even so it is, I think, an example of exalting technique at the expense of judgment even when one appreciates the horror of a fatal pulmonary embolus that occasionally will follow the development of venous thrombosis starting in the calf. This is, after all, a rare happening and its rarity to my mind condemns this treatment and makes ridiculous the practice of one American who ties both femoral veins as a preliminary to abdominal section.

Paravertebral sympathetic block, on the other hand, is a treatment of which I speak with almost unqualified praise. When I first read up the work of Leriche, Ochsner, De Bakey and others I got Mr. Dickson Wright to do a sympathetic block on two patients, one a white leg in pregnancy and the other a similar condition in the puerperium. The relief was

in the posterior tibial veins, as with all abdominal operations and spread up the femoral veins to the iliacs which with their traumatized branches readily join in, and sometimes the lower end of the vena cava and the opposite common iliac are affected. The condition is treated by lumbar ganglionic block, inferior vena cava ligation if pulmonary embolism occurs and possibly in the future by phlebography and thrombectomy. Ligation of the inferior vena cava is also indicated whenever pulmonary embolism occurs after femoral ligation, which is very rarely. It seems opportune to repeat that heparin and dicoumarol therapy is employed in all these post-operative thromboses, and the dosage is 12,500 units of heparin intravenously at 8 a.m., 10,000 at 12 noon, 4 and 8 p.m. and 12,500 at midnight for two days and then the dicoumarol, which has been administered simultaneously by mouth for these two days, takes effect. The dose is 300 mg. the first day, 200 on second and third days and subsequent doses to keep the prothrombin time 220% of normal. The heparin for the first two days should keep the clotting time at twenty minutes. Some surgeons fear dicoumarol and use heparin for the whole of the dangerous period, but the administration is expensive and troublesome for long periods.

Although the legs are the site of nearly all post-operative thromboses, certain cerebral, cardiac, retinal and intestinal thromboses occur at the same intervals after operation as do the leg thromboses, and are really post-operative complications. They are too rare to be treated in anticipation but if occurring after a leg thrombosis, some regrets would be felt if anticoagulants had not been used. Thrombosis of the arm veins following pentothal or venoclysis is annoying rather than dangerous and requires no treatment. Arterial thrombosis after operation occurs in severe degrees of thrombophilia and one such patient who, against my advice, had ligation of varicose veins carried out, suffered the loss of an arm and a leg from this cause. Patients with fibrillation are more prone to form auricular clots after operation and embolize to the systemic arteries. This is especially common after operations for thyrotoxicosis.

The price of freedom from post-operative thrombosis is unrelaxing vigilance. The first signs must be watched for in the proper place, below the calves, under the ribs and on the temperature chart, and there must be no hesitation in applying the proper treatment, drastic as it may seem. It is a well-known fact that the relatives of the person deceased from embolism are prone to be very vindictive, very often without reasonable grounds, but, from now on, they will show even less mercy and may even exact retributions for precautions left untaken.

Mr. Leslie Williams: Though the subject under discussion is post-operative thrombosis much that is said must apply equally to puerperal thrombosis. We gynaecologists have had a sinister reputation in the past, for having our work complicated by venous thrombosis. I do not think that thrombosis nowadays follows gynaecological operating any more than it does general surgical work. Nevertheless, we all do meet cases from time to time and we are still enthusiastic to discuss prophylactic measures and all methods of treatment.

My interest in venous thrombosis was first aroused in the time of the Isolation Block of Queen Charlotte's Hospital. There a few of us, at times, tried to prevent spread of blood-stream infection by ligating veins along which we judged infected clot to be spreading. Sometimes we tied the ovarian vein on one or other side and sometimes the two or three veins which return the blood from the pelvic organs to the iliac trunk. This treatment has become more or less obsolete since the advent of chemotherapy and we are now more interested in thrombosis in veins from the legs.

The whole basis of the modern ideas of treatment of this form of post-operative thrombosis is the knowledge that these thrombi practically always start peripherally in the small deep veins in the calf and almost never in the iliac veins.

At first these thromboses are more or less silent and perhaps at times diagnosable only by intravenous injection of some radiopaque substance and subsequent X-rays. This method has never gained much favour in this country and many regard it as dangerous. In any event it may be unnecessary since I gather from Mr. Dickson Wright that daily palpation of the calf muscles will elicit tenderness in the very early stages of thrombosis and that pain on dorsiflexion of the foot is an equally early and valuable sign.

More commonly we have to deal with an established thrombosis which is recognized by pain as well as early tenderness in the calf, or by the development of "white leg". Sometimes the sudden appearance of pulmonary embolus is the first appreciable sign.

PROPHYLAXIS

In the attempt to minimize the dangers of thrombus formation, the early employment of massage, active and passive movements, &c., is now almost universal. Early rising after labour, the patient perhaps being allowed up on the second or third day, has quite a number of advocates. It has many points to recommend it but the idea is not so popular

leg has occurred. Treatment with anticoagulants does, in my experience, prevent the spread of the thrombosis from the calf to the thigh.

A combination of heparin and dicoumarol is used. Heparin is given by intravenous drip transfusion at a rate of 1,000 to 1,500 international units per hour for forty-eight to seventy-two hours. Dicoumarol is commenced at the same time, as its anticoagulant effect does not occur for two to three days. 300 mg. are given by mouth on the first day and 200 mg. on the second day. Estimations of the prothrombin index are performed daily after the first forty-eight hours. The aim is to lower the prothrombin index to between 40 and 60% of normal, and dicoumarol (usually 100 mg.) is given daily until this level is attained. When the patient is fully ambulant, usually after one week, the dicoumarol is omitted. In the puerperal cases an average of 60,000 I.U. of heparin were given over fifty hours and an average of 1,000 mg. of dicoumarol were given over 6.5 days.

Active exercises are commenced after forty-eight hours, the patient being encouraged to get up as soon as possible. Pain in the leg usually disappears within a few days, so that the patient is anxious to get out of bed.

TOXIC REACTION

There is a certain risk of hæmorrhage occurring from the use of dicoumarol and because of this, accurate estimations of the prothrombin index must be performed daily. In the present series of 11 puerperal deep thromboses only 2 developed a red lochia for a few days, and one of these patients also had a small epistaxis. The incidence of hæmorrhage in all cases treated so far (medical, surgical and obstetric) is about 25%, including minor hæmorrhages. In only one patient was the hæmorrhage serious, however, and she responded well to intravenous vitamin K (150 mg.) and a fresh blood transfusion. With more careful control the incidence of hæmorrhage should be reduced in future.

RESULTS

During the past year 11 cases of puerperal deep thrombosis have been treated and my thanks are due to Mr. J. S. MacVine and Miss M. A. M. Bigby under whose care they were confined. Similar results have also been obtained in the surgical cases. Owing to the very satisfactory results, it did not seem justifiable to use alternate cases as controls. Instead the records of women confined between 1942 and 1946 were surveyed by Mr. R. A. Kinch who found that 16 cases of definite deep thrombosis had occurred during these years. They had all been treated conservatively with complete immobilization. These were compared with the cases treated with anticoagulants for: (1) Length of stay in hospital; (2) length of confinement to bed after the thrombosis had developed.

	Conservative treatment 1942-1946	Anticoagulant treatment 1946-1947
Cases of deep thromboses ..	16	11
Average length of stay in hospital (days)	68	22
(Range)	(26-106)	(10-32)
Average length of confinement to bed after thrombosis (days) ..	45	8
(Range)	(12-100)	(3-12)

The results have also been compared as regards the incidence of pulmonary embolism and as regards the relapse rate of the thrombosis while the patient is in hospital.

	Conservative treatment	Anticoagulant treatment
	16 cases	11 cases
Pulmonary embolism ..	3 (1 fatal)	-
Relapse of thrombosis ..	4	1

It is noticeable, however, that relatively more cases occurred during the past year than in the previous four years as is shown in the following table.

	Incidence of thrombosis 1942-1946	1946-1947
Deliveries	7,147	1,831
Thromboses	16	11
Incidence	0.22%	0.6%

really dramatic. In any successful case the improvement in the general condition of the patient and the local condition of the affected limb is quite striking. The ill, pain-wracked and miserable patient is, within a matter of twenty-four hours, quite a different person. The cold white painful limb is comparatively warm and much less painful, sometimes within half an hour.

It is curious that in these cases of massive thrombosis we have the paradox of a cold swollen limb in a patient whose skin elsewhere is hot; and though the lesion is venous the symptoms and signs are the result of arterial spasm. This spasm is the cause of that damage which makes sympathetic block such a valuable treatment; for by interrupting the reflex, the arterial spasm is relieved, vasodilatation occurs and relief is gained. The same break in the reflex arc can be produced by a spinal anæsthetic, or by a high extradural anæsthetic. But I am advised that the effects produced by these methods may be much more short-lived than those produced by sympathetic block. Once relief of vasospasm is produced by this latter method, the effects appear to be permanent.

The operation itself is far from pleasant. A needle prodding its way along the sides of a vertebral body can be quite offensively painful. And indeed patients dislike the treatment intensely. But once some of the anæsthetic solution has been injected the rest of the operation becomes progressively less painful. Remember, however, that four or sometimes five places are injected.

Sometimes the needle point enters the aorta or the vena cava! It is therefore essential to withdraw the plunger each time before any novocain is injected to be sure of avoiding injection directly into the blood stream.

A great deal of novocain is used—up to 1 gramme. So an occasional toxic effect may be expected. A handy dose of pentothal ready for intravenous injection might come in useful as it would at once abolish novocain convulsions.

Lastly, the method must be applied early—as soon as thrombosis can be diagnosed. It may occasionally give relief in a case of established white leg of several days' duration. But if the treatment is applied early, and if the novocain solution is correctly placed in the neighbourhood of the sympathetic chain by perhaps two or three of the injections, one can be really confident of securing a most remarkable improvement. I highly commend this treatment.

To recapitulate: I strongly recommend immediate intravenous heparin treatment and immediate dicoumarol (temparin) oral treatment together with paravertebral sympathetic block for any patient in whom venous thrombosis in the deep veins of the leg is diagnosed. But I will not, as yet, have anything to do with ligature of the femoral veins, to say nothing of caval ligation.

Dr. K. P. Ball: I should like to describe briefly the treatment of venous thrombosis and pulmonary embolism with the anticoagulant drugs heparin and dicoumarol, which has been in use for the past year at Central Middlesex County Hospital. The 46 cases treated have been drawn from all departments of the hospital—medical, surgical and obstetric—but I shall pay special attention to the cases of thrombosis occurring during the puerperium.

Special stress is laid on the prophylaxis of venous thrombosis by active leg exercises for all patients confined to bed; particularly following childbirth. The early diagnosis of venous thrombosis is considered to be of paramount importance. A careful watch is kept for such early symptoms and signs as pain in the calf which is often worse at night, deep tenderness in the calf muscles, pain in the calf on dorsiflexion of the foot (a sign first described by Homans) and inexplicable temperatures. Following early diagnosis, treatment can be commenced when the thrombosis is limited to the calf and before the fully developed white

employed only for operations of very short duration, particularly those in which there was no great effusion of blood. Its effect on the parturient uterus was quite unknown. When, therefore, Simpson resolved to use ether in midwifery practice—which he did after a visit to his one-time colleague, Liston, the first man in this country to use anæsthesia in surgery—he searched for a case in which a short obstetric operation would be clearly required.

Before long such a case was forthcoming. The patient was a woman with a grossly contracted pelvis; a previous labour had lasted four days and had ended in craniotomy followed by one hour's traction with the crotchet. Contrary to instructions, the woman had not reported the occurrence of this second pregnancy till she had almost reached term, thus precluding treatment by the induction of premature labour. When at length labour-pains became established, Simpson, assisted by Dr. Keith, Dr. Figg and Dr. Zeigler, induced anæsthesia; this successfully accomplished, Simpson proceeded to turn the fœtus by internal version and to extract it in the breech position. Unfortunately, although the infant gasped a few times after birth, full respiration could not be established. It may interest present-day obstetricians to know that the conjugate diameter of this woman's pelvis was estimated to measure no more than $2\frac{1}{2}$ in. and that the baby when born was 8 lb. in weight! The mother, it is recorded, was amazed to find that the long-dreaded delivery had been accomplished while she slept. She made an excellent recovery and was up and dressed on the fifth day.

Pleased, and indeed elated, as Simpson was by the splendid results obtained with sulphuric ether in midwifery, he soon became convinced that other and even better agents might be forthcoming. Accordingly, with his assistants George Skene Keith and James Matthews Duncan, he began a systematic search in which those three workers tested on themselves the effects of inhaling the vapours of a great variety of chemical substances. On November 4, 1847, after much patient and dangerous work the anæsthetic properties of chloroform were discovered—a far better and stronger drug, they believed, than ether. Five days later, this new substance was successfully used in midwifery, and, on the following day, in surgical operations conducted by Professor Miller. Within eleven days Simpson was able to record its administration on no less than 50 occasions. The results were presented for publication on November 15, 1847.

Thus we find that, during this month of November, one hundred years ago, the news of the moment in every medical centre of Britain, of Europe generally, and of America, was the extension of the use of anæsthesia to midwifery practice; and particularly the use of the new drug chloroform—a drug supposedly superior to ether because of the rapidity of its action, the absence of unpleasant choking effects, and the ease and convenience of its administration.

James Young Simpson was the son of a none-too-prosperous baker in the village of Bathgate, eighteen miles from Edinburgh. When he arrived in the University to study Greek and Philosophy he was, by his own statement, "very, very young; very solitary, very poor and most friendless". Seven years later he had graduated as Doctor of Medicine; after eight

R.S.A.)

more years he was appointed, at the age of 28, to the University Chair of Midwifery. Soon, his remarkable powers as clinician, investigator, writer and teacher had made his name one of the best known in the whole medical world. Among earlier honours bestowed on him was his appointment as Physician in Scotland to Her Majesty the Queen. By strange chance, the letter announcing this honour was on its way to him at the very moment when he was administering the first anæsthetic ever to be given to a woman in labour. In a private note written shortly afterwards to his brother, Simpson remarked: "Flattery from the Queen is perhaps *not* common flattery, but I am far less interested in it than in having delivered a woman this week *without* any pain while inhaling sulphuric ether. I can think of nought else."

Simpson's ability for sustained work was amazing. His day started in the early hours of the morning—sometimes as early as 4 a.m.—when he dealt with correspondence and prepared his lecture for the day.

Simpson's interests ranged over the whole field of medicine, and many of our everyday procedures in gynaecology were first described, or perfected by him. He was the first to give an adequate description of the method of bimanual palpation. By introducing the

It is suggested that the difference in the incidence of thrombosis in the two series is due to too few cases being diagnosed from 1942-1946, as the incidence during the past year of 0.6% is itself lower than in many series. Consequently, it must be admitted that the more severe cases from 1942-1946 are being compared with all cases during the past year. But this could only account for a small part of the very striking difference between the two series. Furthermore, the present results showing a reduction of the recumbent period from forty-five days to eight days are confirmed by Bauer (1946). He found that the recumbent period due to the thrombosis had been reduced from forty days in 264 cases with conservative treatment, to 4.7 days in 209 cases using heparin. Zilliacus (1946) found that the stay in bed was reduced from 35.1 days in 214 cases treated conservatively to between 8.1 and 10.5 days in 103 cases, using heparin and dicoumarol together.

In conclusion, I submit that the present treatment shortens the stay in hospital of these patients to about three weeks and the stay in bed to about one week. It has reduced the risk of pulmonary embolism and is likely to diminish greatly the percentage of disabling after-effects which so often cause such distress to these people in later years.

Mr. V. B. Green-Armytage said that the work of Dr. Payling Wright was of sterling importance in the understanding of this condition, but what he would like to ask was why embolism and thrombosis were so rare following pelvic operations from below. This was a fact that had been observed by many American writers and despite the tissue trauma which must follow vaginal hysterectomy, or Fothergill's operation, it was a remarkable fact that complications were very rare. In a series of 4,000 vaginal operations the speaker himself had never seen a case of embolism or thrombosis, though following myomectomy or ordinary laparotomy for gynaecological lesions it was found to occur in one in every 480 cases.

For many years the speaker had never employed the Fowler's position for any kind of gynaecological operation and had made it a constant rule that patients should get out of bed on the third or fourth day. There was no reason why the trauma of vaginal operations should be exempt from thrombosis, whereas that in the closed cavity of the abdomen was so far from exempt.

A Note on the Centenary of the Use of Anæsthesia in Obstetric Practice by J. Y. Simpson

By Professor J. CHASSAR MOIR, F.R.C.O.G., F.R.C.S.Ed.

It is altogether fitting that we in this Section of the Royal Society of Medicine, direct descendants of the oldest Obstetric Society in Britain, should mark and honour the centenary of the event that has probably been the greatest single landmark in the evolution of our specialty. On January 19, 1847, anæsthesia was used for the first time in childbirth. James Young Simpson of Edinburgh was the man concerned, and sulphuric ether was the substance used. The experiment was quickly repeated by Simpson and his colleagues, and soon by obstetricians in widely different medical centres. The subsequent order of events seems to have been as follows. In France, it was first used on January 27 by Fournier-Deschamps. On February 8, it was employed by Baron Dubois who, on February 23, reported its use to the French Academy of Medicine. In London, it was used on February 13 by Dr. Murphy and, later, by Dr. Prothero Smith. In Germany, Professor Martin of Jena used it on February 24, and in America (the birth-place of ether anæsthesia), it was used on April 7 by Dr. Keep of Boston.

By the introduction of anæsthesia into midwifery it became possible not only to lift at will the pain of labour but—and perhaps this was even more important and significant—to employ, in good time, necessary obstetric operations—operations that hitherto, if used at all, had been used as a desperate effort to save a mother's life when all else had failed, and used with the certain knowledge that the patient would thereby be subjected to almost unendurable suffering.

It is perhaps not now clearly realized how daring the deliberate production of insensibility seemed to the workers of those days. It was at first supposed that the method could be

Pes Planus or Instability of the Longitudinal Arch

PRESIDENT'S ADDRESS

By GEORGE PERKINS, M.C., F.R.C.S.

No subject in orthopædic surgery is more muddling than flatfoot. It is a common experience for an orthopædic surgeon to see in his out-patient department hordes of children sent up from school clinics with a diagnosis of pes planus, children who have perfectly normal feet except that their longitudinal arches are low. One is reluctant to send these children away without treatment, because the mothers have been led to believe that treatment is necessary; and one is often persuaded to order remedial exercises and wedged heels solely in order to relieve the anxiety of the parents. I believe that we are swamping our physiotherapy departments with children who do not require treatment, thereby not only wasting the time of the masseuses, but, more important, laying an additional burden on overworked mothers who have quite enough to do in the day without taking their children up to hospital for treatment.

In my view, the popular term "flatfoot" is misleading, since it does not matter whether the longitudinal arch is high or low. A foot with a high arch is just as likely to cause trouble as a foot with a low arch. The presence or absence of symptoms depends on the degree of stability of the arch. A stable arch, whether high or low, is free of symptoms. A foot with an unstable arch is weak and liable to ache. It is unfortunate that the clinical term "pes planus" is so well established, for it would be better to substitute for it the term "instability of the longitudinal arch".

The condition of flatfoot, or instability of the longitudinal arch, cannot be properly understood without a clear understanding of (1) the respective functions of muscles, ligaments and bones, (2) the structure of the longitudinal arch, and (3) how the stability of the arch is normally preserved.

The functions of muscles, ligaments and bones.—Muscles have two functions: (a) to move a joint, and (b) to place and hold a joint in such a position that stress passes directly through its centre. In this respect, muscles act like the staywires of a wireless mast. The staywires do not themselves support the massive weight of the mast, but by their tension hold the mast vertical and by so doing enable the mast to support itself. And if the tension of the staywires was regulated with sufficient nicety, the mast would still support itself in the upright position even if it were joined in the middle (fig. 1). In the case of a wireless mast, the tension of the staywires has to be regulated by an external agency. Muscles, on the other hand, regulate their own tension. This automatic regulation of muscle tension depends on the sensitivity of the joint ligaments.

The ligaments act as watchdogs, giving warning when a joint is being moved beyond a prescribed range. They cannot themselves resist a force except momentarily, and under sustained tension they stretch. As soon as they are stretched they send an S O S via the afferent nerves to the spinal synapses, calling on the muscles to come into action to resist the stretching force (fig. 2).

expanding sponge tent and the uterine sound—in the form we now know that instrument—Simpson made it possible to explore the cavity of the uterus and thus to make the diagnosis of many abnormalities of that organ a matter of scientific certainty rather than of clinical speculation. He was the first in this country to remove the cervix uteri for carcinoma. In addition to a vast output of very able writings, and his many other activities, Simpson could yet devote time to his favourite study of archæology; and his researches into the history of 160 leper houses in Scotland is a contribution still regarded as the most authoritative of its kind in existence.

Living at a time when public controversy and dispute flourished to an extent that is now hardly credible, Simpson was himself a supreme controversialist. Among the many innovations he proposed, or causes he championed, may be mentioned the use of acupressure (a surgical technique devised by himself whereby hæmorrhage from limb amputations could be controlled without the need for dangerous ligatures), and the building of small, airy, easily demolished wards for the treatment of surgical patients. These two recommendations, it should be noted, were made at a time when Listerian surgery was still many years ahead. He advocated a systematic campaign to stamp out zymotic diseases, and he fiercely denounced the doctrines of homœopathic medicine.

To us in these days it seems incredible that there should have been opposition to anæsthesia. Meigs, Professor of Midwifery in Boston, stated: "Anæsthesia is unnecessary as shown by the birth of past myriads"; elsewhere he described labour pains as "a desirable salutary, and conservative manifestation of life-force". Other authorities declared that anæsthesia was "unnatural"; that it was an "unnecessary interference with the providentially arranged process of healthy labour"; that it would certainly increase the mortality of operations; that it might induce convulsions in the pregnant woman; that it might result in the child delivered of a woman under anæsthesia developing into an idiot; that it was "a decoy of Satan apparently offering itself to bless women, but in the end hardening society and robbing God of the deep, earnest cries which arise in the time of trouble, for help". In short, anæsthesia transgressed the scriptural teaching: *in sorrow thou shalt bring forth children*.

Against this very formidable opposition, Simpson brought all his considerable fighting powers to bear. His pamphlet entitled an "Answer to Religious Objections Advanced Against the Employment of Anæsthetic Agents in Midwifery and Surgery" is an outstanding example of his profundity of study, his powers of logic and his scholarly handling of the questions at issue—in this case, philosophical and theological arguments, and the exact meaning of the Hebrew roots of the words from which the relevant passages of our Bible are translated. For several years opinion regarding anæsthesia in childbirth was sharply divided, then news came to an astonished world that Queen Victoria herself, for the birth of her eighth child, Prince Leopold, had had chloroform administered, and had been well pleased with the result. The battle was won.

Simpson died at the age of 59, a victim of angina pectoris. His last illness was precipitated by the rigours of a double journey to London in the coldest weather of winter, made in response to a citation as an expert witness in a medico-legal case.

This is not the time to enter into a discourse concerning the rival merits of ether and chloroform: it is, however, right to pay fresh tribute to the remarkable man who introduced anæsthesia into midwifery and who, with George Keith and Matthews Duncan, later discovered the anæsthetic properties of chloroform. By their work, and by Simpson's unceasing battle against indifference, prejudice and bigotry, the general adoption of anæsthesia was immensely hastened and the scope of surgical and of obstetric operations immeasurably increased.

[Professor JAMES MILLER also read a paper on James Young Simpson which has been published in the *Journal of Obstetrics and Gynæcology of the British Empire*, 1947, 54, 729.]

modifying, for the anterior pillar comprises two prongs, a medial and a lateral. So that, in fact, the longitudinal arch has three main bearing points, the undersurface of the os calcis, the head of the first metatarsal and the head of the fifth metatarsal (fig. 5). When these three bearing points are all on the ground, the foot is said to be plantargrade. (The arch is further strengthened by a cross support—the cuboid—joining the posterior pillar to the lateral anterior pillar, but this is incidental to the present argument.)

For the longitudinal arch to be stable, two conditions must be fulfilled: (1) the body-weight must pass through the centre of the subtaloid-midtarsal joint and (2) when the body-weight is being transmitted through the centre of the subtaloid-midtarsal joint, the foot must be plantargrade, i.e. all three bearing points must be on the ground.

Causes of instability of the longitudinal arch.—The muscle-ligament reflex balancing mechanism, or as it is sometimes called—the postural activity of muscle—is not present at birth, and is gradually acquired during the first year or two of life. When babies first attempt to walk their feet capsize into plano-valgus. Slowly they acquire the knack of balancing their body-weight through the centre of their longitudinal arch, and the plano-valgus disappears. Like the riding of a bicycle, the knack once

FIG. 5.—The three main bearing points of the foot.

FIG. 6.—Varus forefoot.

FIG. 7.—Varus forefoot masked by valgus heel.

learnt is never forgotten, and for the remainder of life the reflex automatically functions whenever the person stands (granted of course that the muscles, ligaments and reflex arc remain healthy). Sometimes, however, the postural activity of muscle is late in developing, and some children persist in standing with their feet in plano-valgus until the age of 3 or 4. Occasionally for some unexplained reason the postural activity of muscle as regards the subtaloid-midtarsal joint is never acquired, and the longitudinal arch remains unstable throughout life, the foot collapsing into plano-valgus whenever the person stands.

Once the postural activity of muscle has been acquired there can be only one reason for pes planus or instability of the longitudinal arch, viz. that the foot, when at right-angles to the leg, is not plantargrade. In a plantargrade foot the three bearing points—the under surface of the os calcis, the ball of the big toe and the ball of the little toe—are in contact with the ground. Two deviations from this orthodox plantargrade position are common: (a) the posterior pillar may be at fault, and the heel does not touch the ground, i.e. there is an equinus deformity, and (b) the medial anterior pillar may be at fault, and the big toe is off the ground, i.e. there is a varus deformity of the forefoot (fig. 6).

The function of *bone* is in no doubt. Bone is constructed to support weight and to assist stress indefinitely; and its lamellæ are parallel to the lines of force likely to be transmitted. Incidentally, when a stress that is not parallel to the lamellæ falls on a bone the bone often breaks. Most fractures are caused by angulation or torsion; rarely does a bone break under a vertical stress.

In the past there has been great argument about whether the longitudinal arch of the foot is supported by muscles or by ligaments. My contention is, that the longitudinal arch supports itself so long as the muscles balance the joints of the arch in such a way that stress passes through the centre of those joints.

The structure of the longitudinal arch.—The longitudinal arch is a composite bony structure designed to transmit the weight of the body to the ground through a wide basis of support. The talus is the keystone of the arch, the os calcis forms the posterior pillar, and the scaphoid, cuneiforms and metatarsals the anterior pillar (fig. 3). Like any architectural arch the human longitudinal arch is able, owing to

FIG. 1.—Hinged wireless mast, held erect by staywires.

FIG. 2.—The ligament-muscle reflex mechanism.

FIG. 3.—The longitudinal arch, in its stable condition.

FIG. 4.—The longitudinal arch, when unstable.

its configuration, to transmit weight without collapsing. When a normal person stands, the weight of his body is transmitted to the ground via the bones of the longitudinal arch; neither ligaments nor muscles transmit any of the stress. One has only to palpate the leg of a standing person to discover that the leg muscles are not in vigorous action. Yet, although the muscles and ligaments do not themselves support any weight, they are essential factors in preserving the stability of the longitudinal arch because the longitudinal arch is a jointed structure. The main joint is a composite affair comprising the subtaloid and the midtarsal articulations. This composite joint capsizes unless weight is transmitted directly through its centre (fig. 4).

When weight is transmitted directly through the centre of the subtaloid-midtarsal joint, all the stress passes through the bones. On the other hand, when weight does not pass directly through the centre of the joint, the ligaments are subjected to tension. The ligaments, on being stretched, reflexly call into action the muscles. Whereupon the muscles alter the position of the subtaloid-midtarsal joint until stress again passes through the centre of the joint. The muscles and ligaments thus form a balancing mechanism which ensures that the weight is transmitted to the ground through the bones without any strain being thrown on the joints of the longitudinal arch.

How the stability of the arch is normally preserved.—I have said that the longitudinal arch consists of a keystone and anterior and posterior pillars. This statement needs

modifying, for the anterior pillar comprises two prongs, a medial and a lateral. So that, in fact, the longitudinal arch has three main bearing points, the undersurface of the os calcis, the head of the first metatarsal and the head of the fifth metatarsal (fig. 5). When these three bearing points are all on the ground, the foot is said to be plantargrade. (The arch is further strengthened by a cross support—the cuboid—joining the posterior pillar to the lateral anterior pillar, but this is incidental to the present argument.)

For the longitudinal arch to be stable, two conditions must be fulfilled: (1) the body-weight must pass through the centre of the subtaloid-midtarsal joint and (2) when the body-weight is being transmitted through the centre of the subtaloid-midtarsal joint, the foot must be plantargrade, i.e. all three bearing points must be on the ground.

Causes of instability of the longitudinal arch.—The muscle-ligament reflex balancing mechanism, or as it is sometimes called—the postural activity of muscle—is not present at birth, and is gradually acquired during the first year or two of life. When babies first attempt to walk their feet capsize into plano-valgus. Slowly they acquire the knack of balancing their body-weight through the centre of their longitudinal arch, and the plano-valgus disappears. Like the riding of a bicycle, the knack once

FIG. 5.—The three main bearing points of the foot.

FIG. 6.—Varus forefoot.

FIG. 7.—Varus forefoot masked by valgus heel.

learnt is never forgotten, and for the remainder of life the reflex automatically functions whenever the person stands (granted of course that the muscles, ligaments and reflex arc remain healthy). Sometimes, however, the postural activity of muscle is late in developing, and some children persist in standing with their feet in plano-valgus until the age of 3 or 4. Occasionally for some unexplained reason the postural activity of muscle as regards the subtaloid-midtarsal joint is never acquired, and the longitudinal arch remains unstable throughout life, the foot collapsing into plano-valgus whenever the person stands.

Once the postural activity of muscle has been acquired there can be only one reason for pes planus or instability of the longitudinal arch, viz. that the foot, when at right-angles to the leg, is not plantargrade. In a plantargrade foot the three bearing points—the under-surface of the os calcis, the ball of the big toe and the ball of the little toe—are in contact with the ground. Two deviations from this orthodox plantargrade position are common: (a) the posterior pillar may be at fault, and the heel does not touch the ground, i.e. there is an equinus deformity, and (b) the medial anterior pillar may be at fault, and the big toe is off the ground, i.e. there is a varus deformity of the forefoot (fig. 6).

An equinus, when present, is compensated for, when the person stands, by dorsiflexion at the subtaloid-mid tarsal joint, but dorsiflexion at this composite joint is accompanied by eversion. Although the foot becomes plantargrade by this means, it does so at the expense of a malalignment of the body-weight, which no longer passes through the centre of the subtaloid-mid tarsal joint.

Varus deformity of the forefoot is compensated for by eversion at the subtaloid-mid tarsal joint (fig. 7) and again the foot is rendered plantargrade at the expense of malalignment of the body-weight.

Equinus has long been recognized as a cause of flatfoot but until recently varus deformity of the forefoot has been overlooked as a causative factor. Both deformities are common. Their origins are obscure. They might result either from a fault in the growth of the tarsal bones, or more likely from the growth of the muscles failing to keep pace with the growth of the skeleton.

In the case of an equinus the calf muscles do not lengthen as quickly as the tibia, and in the case of a varus forefoot the increase in length of the tibialis anticus does not keep pace with the growth of the tibia and tarsus.

Thus, the three main causes of pes planus or instability of the longitudinal arch are: (1) Faulty postural activity of muscle, (2) an equinus deformity of the whole foot, and (3) a varus deformity of the forefoot.

There is, in addition, a congenital type of flatfoot, the skiagram of which shows the talus to be in equinus and the forefoot in marked dorsiflexion. This congenital deformity is rare, and is unlikely to be confused with ordinary pes planus because the shape of the foot is not natural; the sole is boat-shaped. There is also another condition, named spasmodic pes planus, but this is probably an arthritis of the subtaloid joint and not a mechanical instability of the longitudinal arch. The visible muscle spasm and the complete immobility of the subtaloid joint render the diagnosis unmistakable.

SYMPTOMS

The patient, if an adult, complains that his arches have dropped. He has made his own diagnosis and usually brings with him a pair of Scholl's supports which have failed to give him relief. Pain is felt in the sole and along the medial border of the foot, and the feet get hot and sweaty after standing. Stiffness and lameness are complained of, bad first thing in the morning, better during the day and worse again in the evening. There is often aching up the shins, due to over-use of muscles that are trying to protect the sensitive ligaments. A child usually has no symptoms. Either the parent seeks advice on account of the deformity of the child's feet, or else the child is sent up by a school doctor because the feet appear flat.

CLINICAL TYPES

From the point of view of treatment four types of pes planus or instability of the longitudinal arch deserve recognition: (1) Mobile pes planus, due to faulty postural activity of muscle. (2) Mobile pes planus due to an equinus deformity of the whole foot. (3) Mobile pes planus, due to a varus deformity of the forefoot. (4) Rigid pes planus, in which, owing to the faulty transmission of weight through the subtaloid-mid tarsal joint over a long period, the joint wears out prematurely, degenerative changes set in, and the range of movement dwindles on account of an inelastic sclerosis of the joint capsule.

CLINICAL EXAMINATION

Whenever a person has painful feet he imagines he is suffering from pes planus. Frequently he is not. And the first thing to find out is whether there is a pes planus, i.e. whether there is instability of the longitudinal arch, and then to decide on its type.

The examiner investigates four points: (1) When the patient stands, is there instability of the longitudinal arch? (2) If so, does the arch become stable when he tiptoes? (3) When the patient sits, is the subtaloid-midtarsal joint mobile? (4) If so, is the foot plantargrade when the arch is placed in the stable position?

Is the longitudinal arch stable on standing?—The longitudinal arch is stable when the body-weight passes through the centre of the subtaloid-midtarsal joint. Accordingly, the patient is asked to stand with the feet and knees bare, and the line of weight is inspected. A line drawn from the centre of the knee through the middle of the ankle and projected forwards should pass through the second toe (fig. 8). If it does, well and good. There is no instability of the arch. But the converse is not true; the foot may be externally rotated on the leg, that is, the line of the body-weight may pass medial to the medial border of the foot, and yet the arch may be stable. External rotation of the foot can result from the capsizing of the subtaloid-midtarsal joint (fig. 9), and it can result from anatomical anomaly, which may be

FIG. 12.—Normal alignment of body-weight on the right. Eversion of the heel (and therefore instability of the longitudinal arch) on the left.

one of two kinds. In the first, the long axis of the body of the talus points slightly outwards instead of directly forwards (fig. 10). In the second, although the body of the talus is directed straight forwards, the angle the body makes with the neck is abnormal. The anatomists tell us that the neck makes an angle of 140 degrees with the body, so that the anterior surface of the talus which articulates with the scaphoid

faces slightly inwards. In many tali, the angle is nearer 180 degrees than 140 degrees and the anterior articular surface points forwards. Which of these two anomalies is the more common I do not know, but certain it is that in many people, who make no complaint about their feet, the foot is externally rotated on the leg (fig. 11). This external rotation is, in my experience, particularly common among Jews.

What, therefore, we have to decide, in the presence of an externally rotated foot, is whether the external rotation is an anatomical anomaly or whether it is due to a capsizing of the subtaloid-midtarsal joint. To make the decision, one views the standing patient from behind, and draws an imaginary line down the middle of the leg. In the normal person this line deviates slightly outwards at the ankle, but if the os calcis is not directly under the talus, that is, if there is eversion at the subtaloid joint, the line angulates grossly outwards (fig. 12).

It needs to be emphasized that during this examination no attention is paid to the height of the longitudinal arch; all we are concerned with is its stability.

Can the stability of the longitudinal arch be restored?—The patient is asked to stand on tiptoe, and again the line of the body-weight is inspected. If it still passes medial to the second toe, the pes planus is of the rigid type. In the other three types the stability of the longitudinal arch is restored, and the line of the body-weight passes through the second toe.

In the type of pes planus due to faulty postural activity of muscle, the voluntary contraction of the plantar flexors of the foot balances the subtaloid-midtarsal joint so that weight passes through its centre. Stability to the longitudinal arch is likewise automatically restored if the instability is due to an equinus. When the pes planus is caused by a varus deformity of the forefoot, stability is also restored by the vigorous voluntary contractions of the leg muscles, but the patient takes his weight almost entirely through the lateral anterior pillar of the longitudinal arch, and the big toe comes off the ground. With all the weight passing through a single bearing point, the patient is not very steady, and he cannot stand on tiptoe on one foot alone.

Is the subtaloid joint mobile?—The patient is now examined recumbent, with the feet passive. The heel is held by the surgeon in a central position (neither varus nor valgus) and the forefoot placed so that the line of the body-weight passes through the second toe. If this cannot be done, the subtaloid-midtarsal joint has lost its normal mobility, and the pes planus is of the rigid type. There is fixed deformity at the subtaloid-midtarsal joint, which is everted, abducted and dorsiflexed. The eversion is difficult to see because it is masked by a compensatory varus of the forefoot, and the three bearing points are on the same plane. The abduction is made obvious by the uncovering of the neck of the astragalus. On the medial border of the normal foot there is a hollow between the two bony lumps that are formed by the internal malleolus and the tubercle of the navicular respectively. When the foot is abducted the hollow is replaced by a third lump produced by the uncovered neck of the astragalus.

Finally, is the foot plantargrade?—In the three mobile types of pes planus, the foot can be placed so that the line of the body-weight passes through the second toe. The surgeon correctly aligns the foot and then directs his attention to the three bearing points. In pes planus due to faulty postural activity of muscle, the foot is plantargrade, i.e. all three bearing points are in a plane that is at right-angles to the leg and also at right angles to the couch. In the other two types of pes planus the foot is not plantargrade, either an equinus deformity or a varus deformity of the forefoot is disclosed (figs. 13A and 13B).

Clinical signs of the four different types of pes planus.—These may be summarized as follows:

(1) *Pes planus due to faulty postural activity of muscle:* There is malalignment of the body-weight when the patient stands, but this disappears when he tiptoes. In

the recumbent position the foot is mobile, and when the foot is correctly aligned, it is plantargrade.

(2) *Pes planus due to an equinus*: There is malalignment of the body-weight which disappears on tiptoeing. The foot is mobile, but the foot when correctly aligned is in equinus.

(3) *Pes planus due to a varus deformity of the forefoot*: The malalignment of the body-weight disappears on tiptoeing, but the patient finds it hard to balance because he is taking all his weight on a small bearing area. The foot is mobile, but when it is correctly aligned the forefoot is in varus.

(4) *Rigid pes planus*: The malalignment does not disappear when the patient tiptoes. The foot is rigid and cannot be correctly aligned when the patient is recumbent. There is fixed eversion, abduction and dorsiflexion at the subtaloid-midtarsal joint. The foot is, however, plantargrade, for the eversion is compensated for by a varus of the forefoot. There is an accessory lump on the medial border of the foot formed by the uncovering of the neck of the talus.

TREATMENT

For mobile pes planus due to faulty postural activity of muscle.—It is natural for an infant to stand at first with its feet in plano-valgus. Pes planus at this age needs no treatment, for the child gradually acquires the knack of balancing his body-weight through the centre of his subtaloid-midtarsal joint. If postural activity is late in developing and pes planus persists after the age of 2, it is the almost universal practice to wedge the heels of the shoe. But this is a fatuous procedure because a baby's shoe never grips the heel of the foot, which remains in valgus inside the shoe. The deformity is masked not corrected. Wedging of a shoe is justifiable as a placebo when the surgeon feels confident that treatment is not necessary. If treatment is really essential the child must wear boots, which if effectively wedged—and often more than the customary three-sixteenths of an inch is needed—will hold the heel of the foot in varus. Wedging the sole of the boot is unnecessary and often harmful, and moreover makes the sole rigid and renders a toe-and-heel gait difficult. I see no point in the forward prolongation of the heel. It is said that a few children never learn to balance their weight correctly through their feet, with the result that the subtaloid-midtarsal joint becomes hypermobile. Pes planus with hypermobility of this balancing joint is not infrequently seen, but in my experience there is almost always an associated and causative foot deformity, either an equinus or a varus forefoot.

FIG. 13A.

FIG. 13B.

FIG. 13A.—Varus forefoot invisible on account of valgus heel. B.—With heel placed in the central position, varus deformity of the forefoot is disclosed.

FIG. 14.—Shifting of the line of the body-weight laterally by external rotation of the leg.

It has always been customary to treat mobile flatfoot with exercises. A simple exercise is prescribed which the child can carry out many times during the day until

faces slightly inwards. In many tali, the angle is nearer 180 degrees than 140 degrees and the anterior articular surface points forwards. Which of these two anomalies is the more common I do not know, but certain it is that in many people, who make no complaint about their feet, the foot is externally rotated on the leg (fig. 11). This external rotation is, in my experience, particularly common among Jews.

What, therefore, we have to decide, in the presence of an externally rotated foot, is whether the external rotation is an anatomical anomaly or whether it is due to a capsizing of the subtaloid-midtarsal joint. To make the decision, one views the standing patient from behind, and draws an imaginary line down the middle of the leg. In the normal person this line deviates slightly outwards at the ankle, but if the os calcis is not directly under the talus, that is, if there is eversion at the subtaloid joint, the line angulates grossly outwards (fig. 12).

It needs to be emphasized that during this examination no attention is paid to the height of the longitudinal arch; all we are concerned with is its stability.

Can the stability of the longitudinal arch be restored?—The patient is asked to stand on tiptoe, and again the line of the body-weight is inspected. If it still passes medial to the second toe, the pes planus is of the rigid type. In the other three types the stability of the longitudinal arch is restored, and the line of the body-weight passes through the second toe.

In the type of pes planus due to faulty postural activity of muscle, the voluntary contraction of the plantar flexors of the foot balances the subtaloid-midtarsal joint so that weight passes through its centre. Stability to the longitudinal arch is likewise automatically restored if the instability is due to an equinus. When the pes planus is caused by a varus deformity of the forefoot, stability is also restored by the vigorous voluntary contractions of the leg muscles, but the patient takes his weight almost entirely through the lateral anterior pillar of the longitudinal arch, and the big toe comes off the ground. With all the weight passing through a single bearing point, the patient is not very steady, and he cannot stand on tiptoe on one foot alone.

Is the subtaloid joint mobile?—The patient is now examined recumbent, with the feet passive. The heel is held by the surgeon in a central position (neither varus nor valgus) and the forefoot placed so that the line of the body-weight passes through the second toe. If this cannot be done, the subtaloid-midtarsal joint has lost its normal mobility, and the pes planus is of the rigid type. There is fixed deformity at the subtaloid-midtarsal joint, which is everted, abducted and dorsiflexed. The eversion is difficult to see because it is masked by a compensatory varus of the forefoot, and the three bearing points are on the same plane. The abduction is made obvious by the uncovering of the neck of the astragalus. On the medial border of the normal foot there is a hollow between the two bony lumps that are formed by the internal malleolus and the tubercle of the navicular respectively. When the foot is abducted the hollow is replaced by a third lump produced by the uncovered neck of the astragalus.

Finally, is the foot plantargrade?—In the three mobile types of pes planus, the foot can be placed so that the line of the body-weight passes through the second toe. The surgeon correctly aligns the foot and then directs his attention to the three bearing points. In pes planus due to faulty postural activity of muscle, the foot is plantargrade, i.e. all three bearing points are in a plane that is at right-angles to the leg and also at right angles to the couch. In the other two types of pes planus the foot is not plantargrade, either an equinus deformity or a varus deformity of the forefoot is disclosed (figs. 13A and 13B).

Clinical signs of the four different types of pes planus.—These may be summarized as follows:

(1) *Pes planus due to faulty postural activity of muscle:* There is malalignment of the body-weight when the patient stands, but this disappears when he tiptoes. In

the recumbent position the foot is mobile, and when the foot is correctly aligned, it is plantargrade.

(2) *Pes planus due to an equinus*: There is malalignment of the body-weight which disappears on tiptoeing. The foot is mobile, but the foot when correctly aligned is in equinus.

(3) *Pes planus due to a varus deformity of the forefoot*: The malalignment of the body-weight disappears on tiptoeing, but the patient finds it hard to balance because he is taking all his weight on a small bearing area. The foot is mobile, but when it is correctly aligned the forefoot is in varus.

(4) *Rigid pes planus*: The malalignment does not disappear when the patient tiptoes. The foot is rigid and cannot be correctly aligned when the patient is recumbent. There is fixed eversion, abduction and dorsiflexion at the subtaloid-midtarsal joint. The foot is, however, plantargrade, for the eversion is compensated for by a varus of the forefoot. There is an accessory lump on the medial border of the foot formed by the uncovering of the neck of the talus.

TREATMENT

For mobile pes planus due to faulty postural activity of muscle.—It is natural for an infant to stand at first with its feet in plano-valgus. *Pes planus* at this age needs no treatment, for the child gradually acquires the knack of balancing his body-weight through the centre of his subtaloid-midtarsal joint. If postural activity is late in developing and *pes planus* persists after the age of 2, it is the almost universal practice to wedge the heels of the shoe. But this is a fatuous procedure because a baby's shoe never grips the heel of the foot, which remains in valgus inside the shoe. The deformity is masked not corrected. Wedging of a shoe is justifiable as a placebo when the surgeon feels confident that treatment is not necessary. If treatment is really essential the child must wear boots, which if effectively wedged—and often more than the customary three-sixteenths of an inch is needed—will hold the heel of the foot in varus. Wedging the sole of the boot is unnecessary and often harmful, and moreover makes the sole rigid and renders a toe-and-heel gait difficult. I see no point in the forward prolongation of the heel. It is said that a few children never learn to balance their weight correctly through their feet, with the result that the subtaloid-midtarsal joint becomes hypermobile. *Pes planus* with hypermobility of this balancing joint is not infrequently seen, but in my experience there is almost always an associated and causative foot deformity, either an equinus or a varus forefoot.

FIG. 13A.

FIG. 13B.

FIG. 13A.—Varus forefoot invisible on account of valgus heel. B.—With heel placed in the central position, varus deformity of the forefoot is disclosed.

FIG. 14.—Shifting of the line of the body-weight laterally by external rotation of the leg.

It has always been customary to treat mobile flatfoot with exercises. A simple exercise is prescribed which the child can carry out many times during the day until

it becomes automatic; the idea being to encourage the acquisition of an involuntary postural reflex by a conscious voluntary muscle effort. Whether postural activity can be acquired in this way is doubtful. In any case, the usual form of exercise—standing on the outer border of the foot by contracting the *tibialis anticus*—is objectionable because it conduces to a varus forefoot. A better exercise, although more difficult to teach a young child, is to make the patient rotate out the legs while keeping the feet flat on the ground (fig. 14). External rotation of the leg on the foot is equivalent to internal rotation of the foot on the leg, which is what we want to encourage. Making the child stand and walk pigeon-toed is another good exercise.

For pes planus due to an equinus.—It would seem obvious to treat this type of pes planus by exercises designed to stretch the calf muscles. Unfortunately, the stretching force cannot be confined to the ankle-joint and acts also on the subtaloid-midtarsal joint, which it thrusts into eversion, abduction and dorsiflexion. The calf muscles may eventually be lengthened but at the same time the subtaloid-midtarsal joint has been made more wobbly and more difficult for the postural muscle reflex to control. It is better, therefore, in boys, to overcome the equinus by a subcutaneous lengthening of the tendo Achillis; and while the tendon is repairing, to immobilize the foot for six weeks in plaster, with the three bearing points in the same plane, the body-weight correctly aligned, and the foot dorsiflexed to 10 degrees beyond the right-angle. It is by no means easy to apply the plaster with the foot in

FIG. 15.—Two Thomas's wrenches used to correct varus forefoot.

FIG. 16.—Rockered plaster over-boot.

the correct position. Elongation of the tendo Achillis, while not noticeably weakening the calf muscles, does alter the shape of the calf, and the operation is on this account contra-indicated in girls. In them, the equinus should be compensated for by raising the heel of the shoe. This simply anticipates the time when they will naturally wear a high-heel shoe. The rationale of the treatment has to be explained to school mistresses who are apt to object to their pupils not wearing the regulation low-heel shoes of childhood.

For pes planus due to varus forefoot.—We are here dealing with an architectural defect of the longitudinal arch. The arch, when the foot is correctly aligned so that the body-weight passes through the centre of the subtaloid-midtarsal joint, has only two of its three bearing points on the ground; and the problem is to get all three on the ground. This can be done by a forcible manipulation under anaesthesia, at which the medial border of the front part of the foot is thrust downwards. It is interesting to note that some bone-setters empirically use this *manœuvre* in treating flat feet. In resistant cases the aid of two Thomas's wrenches is invoked; one of which grips the os calcis horizontally to hold the heel inverted, while the other grips the forefoot vertically and rotates it into valgus (fig. 15). As a rule it is necessary to immobilize the longitudinal arch in the corrected position for some weeks. Accordingly after the manipulation the foot is put into plaster, with the heel inverted as much as possible, the forefoot everted as much as possible and the whole foot at right-angles

to the leg. The plaster is difficult to apply correctly, and it is helpful to put it on in two stages. The heel is first strapped into full inversion and plastered in this position, and then when this has set the remainder of the foot is included in plaster. A rockered overshoe is fitted over the plaster and the patient is taught to walk with a natural gait (fig. 16). By this means the muscles are prevented from wasting and the joints remain mobile, so that when the plaster is removed at the end of six weeks little rehabilitation is required.

For rigid pes planus.—Here, as well as a structural abnormality of the longitudinal arch there is a fixed deformity at the subtaloid-mid tarsal joint. Both are capable of being remedied by forcible manipulation under anæsthesia; the subtaloid joint can be mobilized, so that the foot is correctly aligned and the body-weight passes through the centre of the subtaloid-mid tarsal joint, and the foot can be made plantargrade by forcible eversion of the forefoot. But often when this has been done movement at the subtaloid-mid tarsal joint is limited and painful, and walking is uncomfortable and remains so until movement is abolished by ankylosing the subtaloid joint. If, however, the subtaloid joint is to be arthrodesed there is no need to correct the alignment of the foot, and even were this necessary it could be accomplished at the same time as the subtaloid-mid tarsal joint was arthrodesed. Therefore, for a rigid pes planus that is causing pain, arthrodesis of the subtaloid-mid tarsal joint is advisable. When the fusion is solid and the foot is released from plaster, the dorsiflexion stress that necessarily accompanies the act of ordinary walking is abolished by rockering the sole of the shoe, as is done in a wooden-soled utility shoe.

Before resorting to an arthrodesis, however, it is worth while seeing whether one can make the patient comfortable by supporting the medial border of his foot. If the upper of the shoe is made rigid, the body-weight can often be transmitted to the ground through the medial border of the foot. Herein lies the value of the rigid foot support. The support is usually made of metal, as in the well-known Scholl's support; but as likely as not this will be superseded in the future by some plastic material which can be moulded to the contour of the medial and under surfaces of the foot. As yet no plastic material of sufficient strength is available.

Mr. W. Sayle-Creer agreed with Mr. Perkins in his advocacy, perhaps unintentional, of more frequent surgical intervention. There were two schools of thought about the maintenance of the long arch—was it by muscles or by ligaments? He felt the application of Sherrington's work on reflex and postural action to the foot had been a disservice to many patients. The experiments of D. J. Morton and Norman Lake suggested the supporting action of the ligaments was of importance. Mr. Perkins had accepted the half-way view of MacConaill that the ligaments were watchdogs and initiated reflex call to muscles if stretched or liable to stretch. But Mr. Perkins had previously demonstrated beautiful results of dividing ligaments to cure the reverse type of condition, talipes equino-cavo-varus. If the ligaments were not important in themselves, where was the need to divide them?

Mr. Perkins stated that the arch supports itself. But this was too ambiguous if unqualified. The stones of an architectural arch were held together by mortar and gravity, and something must hold together the bones of the foot. It might be suction (vacuum) of the joints; more likely it was the ligaments.

He complimented the speaker on his criticism of the term, flat foot. "Instability" was a good description; however, he preferred the American term, *Pronation*, because that described the complicated deformity best. It was stimulating to hear of the other factors, e.g. tightness of tendo Achillis, overaction of tibialis anticus. These were usually overlooked by British writers. He agreed with Mr. Perkins on the ineffectiveness of physiotherapy as usually given. There was no doubt that a surgical operation was much better than surgical footwear in many cases, but he deprecated any rush to operate. However, operations such as those of Lambrinudi were already being done and he felt sure that in future more and more would be performed.

Mr. E. T. Bailey said that in adolescents and adults the symptoms of foot strain ascribed to so-called "flatfoot" were due frequently to imbalance of the foot in a varus position, secondary to a varus deformity of the forefoot. This varus deformity prevented adequate depression of the head of the first metatarsal to the ground by foot pronation, using the term in a descriptive rather than in a strict anatomical sense. Deficient foot pronation meant that the head of the first metatarsal could only be brought to the ground by a valgus tilting of the heel at the sub-astragaloid joint with a resulting valgus deviation of the foot as a whole, giving a typical picture of "flatfoot".

The logical treatment of valgus foot strain lay in foot re-education. For this purpose the usually accepted exercises were inadequate and the assistance of an appropriate exercising machine, such as the Harrens' foot corrector designed for this purpose, could be of material help and had, in practice, proved capable of restoring some 20 to 30 degrees of deficient pronation over a period of some three weeks of treatment.

Sir Thomas Fairbank said he was particularly glad to hear the President refer to fixed inversion of the forefoot on the hindfoot as a factor in many cases. For many years past he had waited in vain for this important point to be referred to in a textbook. This inversion was often difficult to correct. He also welcomed the President's advice that the sole of the boot should not be wedged, but only the heel: he well remembered having an argument with Sir Robert Jones on this point. In young children of over 2 years, he had found the use of removable leather-covered cork valgus insoles in the boots of the greatest value. Though theoretically pressure on the muscles in the sole was inadvisable, he had found these "supports" cure many cases before they were old enough to co-operate in the treatment, a result achieved in only a few cases by simple heel-wedging alone. He preferred postural drill to exercises for the older children. Teaching the child how to stand and walk properly, and persisting in this till the correct posture of the feet had become habitual, he regarded as the only physical treatment of value: ordinary exercises alone he had found of no value.

Mr. J. A. Cholmeley remarked that it was very rare for any shoes or boots to fit a person, particularly a child, closely, as a glove, and in consequence he did not believe that wedging a shoe would have any marked influence on the foot itself but rather that the foot takes up its natural position in the shoe and fitting of an appropriate wedge merely ensures that the shoe or boot shall wear level.

He also stated that at the present time children's footwear is extremely bad and that the soles are generally so stiff that it is necessary to apply considerable force in order to bend them and make them pliable at all.

Mr. J. S. Batchelor said that flatfoot was an unsatisfactory term, for the majority of patients alleged to suffer from this condition showed a postural valgus deformity of the foot without any actual decrease in the height of the long arch. True flatfoot was relatively uncommon and was essentially a congenital deformity.

A valgus foot posture was often associated with an equinus deformity, often rather loosely described as a contracture of the tendo Achillis, and it was unfortunate that the routine remedial exercises usually prescribed strengthen rather than relax the calf muscles. In acute spasmodic valgus, equinus deformity was almost invariably present, and unless this was corrected during the period of immobilization in plaster by placing the foot in a dorsiflexed position, relapse was likely to occur after the plaster was removed.

Mr. V. C. Snell said that he would like to support the suggestion of Mr. Batchelor, that the first group described by Mr. Perkins should not be referred to as "flatfoot", since the deformity occurred at the subastragaloid joint, and there was no actual flattening of the foot itself.

He then referred to the opinions of Mr. McCrae Aitken with regard to this deformity.

When considering postural deformities it must be remembered that the foot is, to some extent, fixed on the ground. The leg moves on the foot, the thigh on the leg, and so on. In consequence, the muscles concerned in maintaining this posture may be regarded as having their origin below and their attachment above.

The astragalus may form part of the leg or part of the foot. In the latter case the tibia hinges on the astragalus and moves backwards or forwards. In the former case the astragalus is locked in the mortice between the tibia and fibula, and together they rotate inwards or outwards on the os calcis.

Normally this internal rotation which would be produced by the body-weight is prevented by the tibialis posticus as it passes round the inner side of the astragalus and behind the medial malleolus. It will occur if the tone of the tibialis posticus is insufficient to oppose the body-weight, and the deformity which we are discussing is thus produced. It is essentially a valgus or internal rotation deformity, and the long arch of the foot is hidden, though the relative position of the bones composing it is little affected.

This same internal rotation underlies hallux valgus, genu valgum, and to some extent postural scoliosis. Each is due to insufficiency of the postural muscles compared with the load they sustain. None of these conditions should really be considered apart from the others.

The tendency to this deformity will be increased by overweight or by insufficiency of tone of the postural muscles which is often due to some illness. If the tibialis posticus remains insufficient the patient may attempt to relieve the strain by using the tibialis anticus and the long extensor of the big toe, neither of which is designed to maintain posture. This may underlie the deformity also described by Mr. Perkins where there is a varus deformity of the forefoot.

As regards treatment, if the valgus position is corrected when the patient stands on tiptoe (i.e. on active contraction of the tibialis posticus) it is enough to relieve the strain on this muscle by heel wedges until it has had time to get stronger. Heel wedges are efficient if care is taken that the shoes fit adequately around the hindfoot.

Clinical Section

President—G. E. VILVANDRÉ

[October 10, 1947]

Two Cases of Coarctation of Aorta.—A. DICKSON WRIGHT, M.S.

I.—Miss A., aged 33; land worker.

Family history.—Not significant. As a child she suffered from bilious attacks. Eight years ago intermittent encephalopathic symptoms appeared and were often quite disabling. The headaches were a general pain over the head associated with vomiting and were relieved by bandaging the head tightly. The vertigo was sometimes very severe and even caused fainting. The eyes were watery and the vision blurred. The legs were noticed to be cold in their lower halves and walking caused claudication. Pounding of the heart was a distressing symptom and interfered with sleep, and anginal pains radiating into both arms and breathlessness on exertion were diagnosed as asthma.

On examination.—Loud systolic murmur could be heard over the whole area of heart but was loudest posteriorly. Collateral vessels seen pulsating on chest and in scapular region when patient bent forward (Susman's sign) and the murmur was conducted along these vessels. The radial pulses were equal and normal but the femoral pulses could not be felt. Blood-pressure was elevated but labile, at times it exceeded 300 but after rest in bed for seven days it fell to 140. With sodium amytal test it fell significantly. X-ray showed absence of aortic bulge and notching of ribs (4, 5, 6) and the descending aorta below coarctation dilated. Blood urea 33 mg.

Although referred for sympathectomy, resection of the stenosis was thought preferable and from this she made a good recovery. The blood-pressure is now normal; and pulses at the ankle are easily felt. There was still a slight murmur in the region, and this was expected as the aorta above the coarctation was only about half the diameter of the descending aorta. This murmur has now disappeared.

II.—Miss C., aged 36; secretary.

Family history.—Her mother, who died suddenly at 70, had all her life, visible pulsation in the neck such as the patient displayed. Patient's symptoms for past six years consisted of periodic attacks of blurring of vision, pounding of heart and visible pulsation in the neck. The blood-pressure labile, sometimes as low as 160 and very often as high as 370 mm.Hg. The eye grounds showed silver wire arteries and pallor of the retina. X-ray of the thorax showed the usual picture of no aortic knuckle and indentations of the lower rib margins. Blood urea 44 mg. Femoral pulses could only be felt with difficulty and were delayed as compared with radial pulse. Blood-pressure in legs were about one-half of arm pressures. Loud systolic murmur. Susman's sign was well shown in addition.

The patient had come in to hospital for ligature of varicose veins but consented to the major procedure.

The operation was straightforward except that the ductus was quite patent and as much blood seemed to traverse this as the aortic stenosis. The ductus was ligatured and divided and the aortic stricture excised after mobilization of the aorta which was effected by ligature and division of the enlarged intercostal arteries. Recovery was uneventful and after ten days the varicose veins were ligatured. The patient was discharged on the fourteenth day with normal ankle pulses and blood-pressure. The neck pulsation persists but is not so obvious, the visual troubles have disappeared and the palpitation no longer disturbs her rest.

JAN.—CLIN. 1.

The logical treatment of valgus foot strain lay in foot re-education. For this purpose the usually accepted exercises were inadequate and the assistance of an appropriate exercising machine, such as the Harrens' foot corrector designed for this purpose, could be of material help and had, in practice, proved capable of restoring some 20 to 30 degrees of deficient pronation over a period of some three weeks of treatment.

Sir Thomas Fairbank said he was particularly glad to hear the President refer to fixed inversion of the forefoot on the hindfoot as a factor in many cases. For many years past he had waited in vain for this important point to be referred to in a textbook. This inversion was often difficult to correct. He also welcomed the President's advice that the sole of the boot should not be wedged, but only the heel: he well remembered having an argument with Sir Robert Jones on this point. In young children of over 2 years, he had found the use of removable leather-covered cork valgus insoles in the boots of the greatest value. Though theoretically pressure on the muscles in the sole was inadvisable, he had found these "supports" cure many cases before they were old enough to co-operate in the treatment, a result achieved in only a few cases by simple heel-wedging alone. He preferred postural drill to exercises for the older children. Teaching the child how to stand and walk properly, and persisting in this till the correct posture of the feet had become habitual, he regarded as the only physical treatment of value: ordinary exercises alone he had found of no value.

Mr. J. A. Cholmeley remarked that it was very rare for any shoes or boots to fit a person, particularly a child, closely, as a glove, and in consequence he did not believe that wedging a shoe would have any marked influence on the foot itself but rather that the foot takes up its natural position in the shoe and fitting of an appropriate wedge merely ensures that the shoe or boot shall wear level.

He also stated that at the present time children's footwear is extremely bad and that the soles are generally so stiff that it is necessary to apply considerable force in order to bend them and make them pliable at all.

Mr. J. S. Batchelor said that flatfoot was an unsatisfactory term, for the majority of patients alleged to suffer from this condition showed a postural valgus deformity of the foot without any actual decrease in the height of the long arch. True flatfoot was relatively uncommon and was essentially a congenital deformity.

A valgus foot posture was often associated with an equinus deformity, often rather loosely described as a contracture of the tendo Achillis, and it was unfortunate that the routine remedial exercises usually prescribed strengthen rather than relax the calf muscles. In acute spasmodic valgus, equinus deformity was almost invariably present, and unless this was corrected during the period of immobilization in plaster by placing the foot in a dorsiflexed position, relapse was likely to occur after the plaster was removed.

Mr. V. C. Snell said that he would like to support the suggestion of Mr. Batchelor, that the first group described by Mr. Perkins should not be referred to as "flatfoot", since the deformity occurred at the subastragaloid joint, and there was no actual flattening of the foot itself.

He then referred to the opinions of Mr. McCrae Aitken with regard to this deformity.

When considering postural deformities it must be remembered that the foot is, to some extent, fixed on the ground. The leg moves on the foot, the thigh on the leg, and so on. In consequence, the muscles concerned in maintaining this posture may be regarded as having their origin below and their attachment above.

The astragalus may form part of the leg or part of the foot. In the latter case the tibia hinges on the astragalus and moves backwards or forwards. In the former case the astragalus is locked in the mortice between the tibia and fibula, and together they rotate inwards or outwards on the os calcis.

Normally this internal rotation which would be produced by the body-weight is prevented by the tibialis posticus as it passes round the inner side of the astragalus and behind the medial malleolus. It will occur if the tone of the tibialis posticus is insufficient to oppose the body-weight, and the deformity which we are discussing is thus produced. It is essentially a valgus or internal rotation deformity, and the long arch of the foot is hidden, though the relative position of the bones composing it is little affected.

This same internal rotation underlies hallux valgus, genu valgum, and to some extent postural scoliosis. Each is due to insufficiency of the postural muscles compared with the load they sustain. None of these conditions should really be considered apart from the others.

The tendency to this deformity will be increased by overweight or by insufficiency of tone of the postural muscles which is often due to some illness. If the tibialis posticus remains insufficient the patient may attempt to relieve the strain by using the tibialis anticus and the long extensor of the big toe, neither of which is designed to maintain posture. This may underlie the deformity also described by Mr. Perkins where there is a varus deformity of the forefoot.

As regards treatment, if the valgus position is corrected when the patient stands on tiptoe (i.e. on active contraction of the tibialis posticus) it is enough to relieve the strain on this muscle by heel wedges until it has had time to get stronger. Heel wedges are efficient if care is taken that the shoes fit adequately around the hindfoot.

FIG. 1.

Treatment by transfusions, fersolate and multivite: with routine treatment of amœbiasis.

Operation (Mr. Forrester Wood) on August 11, 1947: Elective total gastrectomy by abdomino-thoracic approach. The stomach was much enlarged and had the texture of an enormous varicocele. The pre-operative diagnosis had been probable diffuse neoplasm, and removal was performed as planned.

Comment.—This is a typical example of giant hypertrophic gastritis (Maimon, *et al.*) and the photograph (fig. 1) shows the characteristic appearance of "cerebral convolutions" described in the early reports of the condition by Menetrier. No characteristic symptoms attach to the condition, and its relation to the commoner cases of localized giant rugæ is uncertain. The patient's present condition is excellent.

REFERENCE

MAIMON, BARTLETT, HUMPHREY AND PALMER (1947) Giant Hypertrophic Gastritis, *Gastro-enterology*, 8, 397.

Sclerodactylia with Œsophageal Lesion.—W. A. BOURNE, M.D. (*see Proc. R. Soc. Med.*, 1947, 40, 463. Case I).

The patient developed increasing dysphagia apparently due to pharyngeal inco-ordination, and died suddenly.

Post-mortem examination.—Externally, fairly marked kyphosis with finger nails deformed and brittle and the skin over the thenar eminences and forearms thickened and desquamating. Internally, *tongue smooth*: *œsophagus*, the upper end appeared normal but at the lower end its gross appearance was peculiar, with gradually increasing thickness and opacity of the epithelium, which became white and coarse in texture (leukoplakia) down to the œsophago-gastric junction. This was clearly defined by a sharp transition from the white œsophageal mucosa to the normal-coloured gastric mucosa. A small scar in the lower œsophagus appeared to indicate the site of a healed ulcer. There was a fairly marked hernia of the stomach through the œsophageal hiatus. *Lungs*, basal œdema and early bronchopneumonia; fine bilateral pleural adhesions. *Heart*, very small, the myocardium brown and atrophic, with pericardial thickening and adhesions between visceral and parietal layers. *Small and large intestine*, a curious appearance—generalized thinning and dilatation of the walls of the gut so that it appeared paper thin and of an opaque yellowish colour. There was dilatation of the lacteals, which were visible running through the mesentery. The sigmoid colon showed a few diverticula.

Microscopically, the œsophagus shows little abnormality. The covering epithelium tends to be hyperplastic but has much variation in the depth of the squamous layer. There is patchy round-celled perivascular infiltration in the corium. *Pericardium*: similar perivascular infiltration with hyperplasia of the muscle-cells of the medium-sized vessels. *Myocardium*: fibrous tissue increase and patchy muscle-cell destruction with replacement in some areas by a fine collagenous matrix. *Intestine and mesentery*: no definite histological abnormality.

Comment.—In addition to gross changes in the hands there is evidence of a diffuse change affecting the intestinal tract and pericardium and probably heart muscle and pleura. A clinical diagnosis of small intestine involvement had been made and macroscopical evidence of lacteal obstruction supported this, though clear histological demonstration of excess of collagenous tissue in the mesentery seems difficult in the absence of normal standards. The case is important as an example of the association of sclerodactylia with visceral lesions, which are less common, less demonstrable, or have less time to develop, in diffuse scleroderma with its probably more rapid course.

Myelosclerosis.—D. G. FERRIMAN, D.M.

F. B., a boy aged 13 years, was admitted to the North Middlesex County Hospital on 17.4.47 complaining of pallor and weakness for one week following coryza two weeks beforehand.

Cooley's Anæmia.—J. RUBIE, M.B., M.R.C.P. (for Dr. A. JACOBS).

FIG. 1.

Cooley's anæmia—typical facies.

E. P., aged 9 months. Admitted at 3 months with cough and persistent chronic rhinitis.

Points of interest are.—Parents are Cypriots. The child has anæmia. Blood-count after two months' iron was R.B.C. 5,220,000; Hb 60%; C.I. 0.58; W.B.C. 17,000 (polys. 59%, eosinos. 1%, lymphos. 29%, large monos. 11%); reticulocytes less than 1%; i.e. low Hb and leucocytosis. Target cells in film. R.B.C. show marked decreased fragility—hemolysis commenced 0.32% NaCl, complete at 0.12% NaCl. Mongoloid facies (see figure), muddy complexion. Spleen just palpable. Marrow shows normoblastic hyperplasia. W.R. negative. X-ray of skull shows early changes in frontal bone—the characteristic spicule formation—and there is probably some rarefaction of heads of femora. The father and one sister show target cells in peripheral blood, two other children and the mother normal.

This case was thought to be a mild variety of Cooley's anæmia, as found in heterozygous children. After iron therapy for six months the Hb is 64%.

Dr. Arnold H. Banton (*in absentia*) said that although rare in Europe the disease was relatively common in Cyprus. He had recently conducted an investigation of the condition among Cypriots in their native land, the results of which he hoped would shortly be published.

It was important to differentiate between the "trait" and the disease. He found the trait exhibited by about 20% of the Cypriot population, a figure which agrees fairly closely with Fawdry's findings. The essential features of the trait were a normal hemoglobin, but the blood picture may show anisocytosis, poikilocytosis and usually "target" cells, and increased resistance to hypotonic saline. It is believed that the trait is inherited not as a Mendelian dominant, as was formerly supposed, but as an abnormal recessive.

The fully fledged disease usually occurs in the children of parents both of whom show the trait, but not all the children of such a union are necessarily affected.

Dr. Banton mentioned two clinical features which he had observed: (1) premature closure of the fontanelle; and (2) ulceration of the shins, recurrent and slow in healing. This last was not distinctive of Cooley's anæmia but occurred in other chronic hemolytic anæmia such as acholuric jaundice. Bone changes were seldom seen in those who exhibited the trait only.

Giant Hypertrophic Gastritis.—W. A. BOURNE, M.D., and W. R. FORRESTER WOOD, F.R.C.S.

Male, lorry driver, aged 27, admitted to the Royal Sussex County Hospital with a month's history of progressive loss of weight, increasing dyspnoea, oedema of ankles, and vague dyspeptic symptoms, dating from a brief attack five months before admission of epigastric pain one hour after food, with nausea. Since then the appetite had been poor. For five months there had been increasing palpitation, lassitude and pallor.

Past history of appendicectomy and peritonitis, 1937; malaria 1943; and mild attacks of diarrhoea at that time.

Family history.—Mother's death at 44 from "heart failure"; nothing otherwise notable. Tobacco consumption, 20 cigarettes daily; alcohol consumption very small.

Clinically there was pallor, oedema of ankles and over sacrum, rhonchi and râles at the right lung base; and, except for a paramedian scar, no abdominal abnormality.

Special investigations.—Blood: R.B.C. 2,900,000; Hb 26%; C.I. 0.46 (the red cells showed marked hypochromasia and polychromasia with poikilocytes, microcytes and a few monocytes); W.B.C. 10,300 (neutros. 52%, lymphos. 43%, eosinos. 1%, monos. 4%). Fragility, clotting and bleeding time normal. W.R. (blood) negative. No malarial parasites seen. No occult blood in one specimen of faeces. Histamine test meal within normal limits, maximum free acidity 50%. *Entamoeba histolytica* in vegetative and encysted forms in stools. Barium meal, multiple filling defects along the whole of the greater curve. Gastroscopy, large nodular protuberances covered by reddened mucosa.

Section of Medicine

President—MAURICE DAVIDSON, M.D.

[October 28, 1947]

DISCUSSION ON CHEMOTHERAPY IN MALIGNANT DISEASE

Professor Alexander Haddow: Although the need for an efficient chemotherapy is measured by the limitations of surgery and radiotherapy, the student of cancer cannot but be impressed—since he is best qualified to judge them—by the manifold difficulties which the subject presents. The main difficulties arise from the fact that the cancer cell is but a modification of the normal, that conversion to malignancy may be due to a re-orientation of enzyme constitution quite unaccompanied by any gross changes affecting protein structure or immunological specificity, that there is on this account no protective reaction on the part of the body such as occurs in infections, and that the malignant state appears highly stable, if not irreversible. It seems probable that the normal and malignant stages are separated by an energy barrier, and the ideal chemotherapy, that is the re-conversion from malignant to normal, would hence demand the application to the malignant cell of an amount of energy probably greater than that required for the original conversion, and in a way which is quite beyond our powers at the moment. Apart from this ultimate objective, we are nevertheless already able to achieve useful if limited therapeutic effects by other means, as in the treatment of carcinoma of the prostate with œstrogens, and through the action of the chloroethylamines in Hodgkin's disease and of urethane in leukæmia. It is not without interest that all these developments have arisen entirely naturally, through the pursuit of observations either incidentally or for their own sake, and without any immediate thought of practical application.

I was particularly struck by this in a recent discussion with Dr. Charles Huggins in Chicago, when he described to me the influence upon later work of his early experience at the Lister Institute, working with Robison on phosphatases. So, too, it is well known how the cytotoxic effects of the chloroethylamines, on tissues in a state of active proliferation, were recognized from chemical warfare studies of the nitrogen analogues of mustard gas (*see* A. Gilman and F. S. Philips, *Science*, 1946, 103, 409). In discussion of a recent paper by J. F. Wilkinson and F. Fletcher (*Lancet*, 1947 (ii), 540), on alkylamines in the treatment of leukæmia and Hodgkin's disease, Dr. Ff. Roberts is of the opinion (*Lancet*, 1947 (ii), 634) that these agents have little future, and that they may prove a disastrous failure as compared with radiation. It may, however, be that practical assay and comparison are not important at this early stage, and certainly our attention should not be deflected from effects which are, as experiment shows, of remarkable interest in themselves. A similar situation is found in the case of urethane. Following early accounts of phenyl urethane as a mitotic poison, Templeman and Sexton had studied the effects of various arylcarbamic esters on cereals and other plant species, when the production by several of these agents of characteristic effects on nuclear division, with resulting inhibition of growth, led to their use in the elimination of graminaceous weeds. Similar work in animals (Haddow and Sexton, *Nature*, 1946, 157, 500), led to the discovery that urethane itself can be regarded as a mitotic poison and produces inhibitory effects upon the growth of various animal tumours. Then followed a clinical trial which was largely negative until the further discovery of the radiomimetic action of urethane in leukæmia (Paterson, Ap Thomas, Haddow and Watkinson, *Lancet*, 1946 (i), 677).

All these developments are of interest and promise, and it must therefore continue to be our duty to encourage the study of what for want of a better term we may call the chemotherapy of cancer.

On examination he was pale and had slight but definite icterus; the spleen was enlarged 1½ in. below the level of the umbilicus; the liver was not enlarged; lymph glands were readily palpable but not definitely enlarged. 18.4.47: Hb 43%; R.B.C. 2,050,000; nucleated cells 28,000; polys. 23%; myelocytes and metamyelocytes 12%; myeloblasts 9%; normoblasts 30%; monos. 3%; lymphos. 20%; lymphoblasts 3%. (This leuco-erythroblastic reaction has been seen in all subsequent counts.) 19.4.47: Serum bilirubin 1.5 mg.%; 27.4.47: Reticulocytes 4.2%; Hb 50%; R.B.C. 2,820,000; packed cell volume 24.5%; mean corpuscular volume 8.7 cu. μ ; mean corpuscular Hb concentration 28%; mean corpuscular diameter 7.2 μ . Subsequent investigations.—W.R. negative, fragility R.B.C. normal, Bence-Jones protein absent, sternal puncture failed twice, bleeding and coagulation times normal. X-ray of bones—multiple punched-out areas of infiltration bone and bone-marrow (fig. 1). 3.6.47: Biopsy of deposit in right femur (Mr. Hedley Hall), white fibrous nodule lifted out of cavity in *corticalis*. Histological examination (Dr. J. F. Heggie) revealed "fibrocellular-osteoid combination which shows osteoclastic activity and fibrous replacement of the bony trabeculae most of which show resorption of calcium salts and have reached osteoid state" (fig. 2).

FIG. 1.—F. B. X-ray of right femur.

FIG. 2.—F. B. Section of fibrous nodule in bone ($\times 135$).

(Photographs by E. W. Hall, A.R.P.S.)

Progress and treatment.—Icterus disappeared within a few days of admission. Given blood transfusions and iron. Hb rose steadily to 80%. Low fever present throughout admission. 14.7.47: Hb 68%. Testosterone propionate—5 mg. twice a week—started 15.7.47. 5.9.47: Hb 72%; R.B.C. 4,020,000; nucleated cells 57,000; polys. 7%, myelocytes and metamyelocytes 57%, myeloblasts 25%, lymphos. 4%, lymphoblasts less than 1%, monoblasts less than 1%, erythroblasts 5%, platelets 278,000. The spleen is now grossly enlarged coming to within 1 in. of the right superior iliac spine.

Dr. C. J. C. Britton has suggested a diagnosis of myelosclerosis in this case.

Dr. F. Parkes Weber said that the skiagrams of the long bones made him think of what he would call "Polyostotic focal fibrous dysplasia" (not connected with hyperparathyroidism), but he had never heard of this condition being accompanied by a blood picture of leuco-erythroblastic anaemia.

Dr. Herbert Levy agreed that this was a case of myelosclerosis. The suggestion of polyostotic fibrous dysplasia could not be upheld as that condition never leads to leuco-erythroblastic anaemia and splenomegaly; moreover, in contrast to the present case, the bony lesions tend to be unilateral and show histologically minimal osteoclastic resorption. He also agreed that there was good reason to adhere to the view that the splenic enlargement is compensatory and that splenectomy cannot therefore be contemplated.

mitosis has been obtained with both materials which resembles that of X-rays and differs from that of colchicine in that no effect on the spindle has been observed.

Spores soaked for six hours in 0.5% urethane show less effect than if given 1,000 r X-rays; fibroblasts soaked for twenty-four hours in a 0.1% concentration show similar effects to those given 30 r X-rays. In tissue cultures no augmentation of effect has been found by combining urethane and X-rays, the effect of X-rays being lessened if urethane is administered after radiation. In fern spores this lessened effect of radiation is also obtained if urethane is administered first, but not when given after irradiation. So far the work shows that urethane acts directly on the cell; that mitosis is inhibited and differentiation is induced. The similarity of urethane and X-ray effects suggests the possibility that urethane may be also capable of inducing changes in chromosomes.

Dr. Inez Ap Thomas: Nitrogen mustard therapy.—The following is a summary of our results of treatment with nitrogen mustard. The compound used in most cases was methyl-bis (B-chloroethyl) amine hydrochloride. Only a few received tris (B-chloroethyl) amine hydrochloride. The total number treated is 41. 27 of these were cases of Hodgkin's disease, proved by section. The treatment is not curative, and the aim is to produce symptomatic improvement.

A summary of the improvement is shown in Tables I and II.

TABLE I.—RESULTS OF FIRST COURSE OF NITROGEN MUSTARD TREATMENT IN 27 CASES OF HODGKIN'S DISEASE.

Sign or symptom	Total	Improved	% improved
Enlarged nodes	23	21	92
Enlarged mediastinum	7	7	100
Enlarged abdomen	7	7	100
Enlarged spleen	4	4	100
Poor general condition.. ..	18	18	100
Pyrexia	13	10	77
Skin rash	2	2	100
Pain	5	5	100
C.N.S. involvement	1	0	0

TABLE II.—PERCENTAGE IMPROVEMENT IN ALL SYMPTOMS IN PATIENTS UNDER NITROGEN MUSTARD TREATMENT

1st course 27 cases	2nd course 16 cases	3rd course 8 cases	4th course 1 case	fortnightly 3 cases
92%	73%	60%	100%	100%

Improvement was not maintained, but the patient improved again with further treatment. The total dose in most cases was 0.4 mg./kg. of body-weight in two days (two injections) for the first course. In later courses this was increased to 0.6 mg./kg. in two days. Later courses were given of 0.1 mg./kg. at fortnightly intervals.

Leucopenia followed treatment but this was temporary. It was occasionally serious as in one case treated with tris (B-chloroethyl) amine hydrochloride, where the total white blood-count fell to 200, the hæmoglobin to 40% and platelets to about 11,000. Several blood transfusions were necessary for recovery.

In our series other reticuloses and malignant tumours did not respond well, though carcinoma lung did improve temporarily.

The report is a confirmation that the nitrogen mustards are of value in Hodgkin's disease when radiation treatment is not practicable, but that they should not be used as an alternative to X-ray therapy in early cases, since the remissions with nitrogen mustard are shorter and the toxic effects more severe.

Mr. E. W. Riches (Middlesex Hospital): My remarks will be confined to the use of synthetic oestrogens in the treatment of carcinoma of the prostate. In this disease there is no doubt that such treatment is beneficial and the immediate results are

Dr. Edith Paterson: *Urethane in leukaemia.*—The previous work done on the effect of urethane in leukaemia has been extended and information has been gained on the effect of urethane on cells.

No beneficial effect has been obtained in acute or terminal cases of leukaemia, although in the former a very temporary improvement in the blood occurs. In chronic leukaemia the results have been good both in improving the general condition of the patient and in altering the blood towards the normal. This improvement is indistinguishable from that which follows the usual method of treatment by splenic irradiation.

In the myeloid type the white cell count has fallen in every case. Typically the reduction in white cells is accompanied by a rise in hæmoglobin, and the differential count also approaches normal. In most cases the myeloblasts disappeared. In a few patients a rise in metamyelocytes occurred at the expense of a decrease of more primitive forms. This suggests that one effect of urethane is to promote differentiation.

The rise in red cells coincides with the diminution of a high white cell count. The amount of the rise is important in assessing the prognosis. About half of the cases showed an immediate rise in hæmoglobin which exceeded 10%; the remainder showed a lesser rise, or fell. In the former group the expectation of life has been more than twice that in the latter group. The effect of urethane on the platelet count was parallel to that on the red cells. A low platelet count rose; a high platelet count either remained stationary or rose. The bone-marrow responded similarly to peripheral blood; erythropoiesis increased with a diminution of myeloid cells. As with X-ray therapy the spleen diminished in size in every case and in some instances became impalpable.

In chronic lymphatic leukaemia the effects are similar, but differences exist. The white cell count falls, but probably with less constancy than in myeloid leukaemia. The differential count improves; the polymorphs increase and lymphoblasts tend to disappear. The hæmoglobin rises after treatment, but unlike myeloid leukaemia the rise does not bear a clear relationship to prognosis. A low platelet count is a usual finding in these cases; after treatment this either rose or remained stationary. No parallelism was found between the rise in hæmoglobin and the effect on the platelets. As with myeloid leukaemia the marrow in lymphatic leukaemia showed an increase in the proportion of nucleated red cells. Since this occurred even when the peripheral red cell count was satisfactory, it illustrates the need for examination of the marrow in lymphatic leukaemia before judging suitability for treatment. Diminution in the size of the spleen and lymph nodes was less constant than in myeloid leukaemia.

Experience has shown that urethane can be regarded as an alternative to X-ray treatment in leukaemia. As with X-rays, the urethane treatment of leukaemia may present difficulties. Nausea occurs in some cases, but in these the drug may be given in capsule form, or rectally in saline. The intravenous method used by Storti and Mauri has also been found useful. An excessive dose of urethane may result in aplasia of the bone-marrow with leukopenia and a fall in hæmoglobin and in platelets.

Post-mortem examinations have been carried out in a number of urethane treated cases, and the findings compared with those of a similar sample of patients treated by X-rays. The causes of death were the same in the two groups; about one-third of the patients died of infection, including tubercle; the remainder died of the usual sequels of leukaemia. Two cases treated by urethane showed a moderate degree of fibrosis of the marrow. Another showed excessive organization of old pneumonic areas. It is uncertain whether either of these changes is a specific effect of urethane.

Experimental work has been carried out on the effect of urethane on normal and malignant cells and the combined effect of urethane and X-rays. Spontaneous mammary tumours in mice show a temporary regression. The effect on normal cells has been tested on fern spores and on fibroblasts *in vitro*. An inhibition of

in the expectation of life and in particular to reduce the alarming mortality of the first year.

Dosage.—It is my practice to start with 1 mg. of stilbœstrol t.d.s. and increase the dose daily by 1 mg. t.d.s. up to 5 mg. t.d.s. The patient remains on 15 mg. daily for a variable number of weeks or months; occasionally 20 mg. daily is given. Provided that the serum acid phosphatase remains normal the dose is gradually reduced. The adequate maintenance dose is assessed by the general and local condition and by the level of serum acid phosphatase. It is never less than 1 mg. daily and may remain at 15 mg. daily. In a very few cases stilbœstrol has produced nausea or vomiting and dienœstrol has been substituted but my impression is that it is less effective than stilbœstrol. However, I have one patient surviving four years and five months who has taken dienœstrol throughout.

The value of the serum acid phosphatase is variable, but I consider that it should be estimated before any œstrogen is given. If raised, as when osseous metastases are present, its subsequent fall is an index of response and a guide to the correct maintenance dose. If the dose is inadequate the acid phosphatase rises again, and this may be an indication of further metastases (graph 2).

FIG. 2.—Pigmentation of nipple produced by œstrogens.

well known. There are, however, differences of opinion on the number who respond, the duration of the benefit, the proper dosage, and the general management of a case including the need for adjuvant surgical treatment. In order to try and answer these questions I have reviewed all my cases treated for a minimum of three years. I started using stilbæstrol early in 1943, stimulated by a paper by Professor Haddow read at the Faculty of Radiologists (1943).

There are 16 cases treated for four years and upwards, and 24 treated for three years and upwards, a total of 40. At the same meeting I reported on 70 cases treated before stilbæstrol came into use so that I have figures for comparison (Riches, 1943). In 37 of the 40 the diagnosis has been verified histologically, and in the other 3 by the presence of osseous metastases, and a high acid phosphatase.

There are two clinical varieties of carcinoma of the prostate, the primary scirrhus and the adenocarcinoma arising secondarily in a gland which is the seat of benign hypertrophy. The former usually starts in the posterior lobe and is easily recognized as being malignant from the outset. It occurs at a younger age than the adenocarcinoma, and is more lethal. The secondary type may not be discovered until the gland is examined microscopically after its removal for benign hypertrophy, and the patient may then live for ten years or more without other treatment before getting a recurrence. Complete cure is only likely in this type, and it will naturally give better statistical results after stilbæstrol just as after any other method of treatment. Unfortunately there is no marked histological difference between the two, and the distinction is purely clinical. Hence most statistics group them both together and this renders the assessment of results of treatment open to misinterpretation.

Pre-æstrogen results.—The average five-year survival rate before stilbæstrol was about 7% from all methods of treatment.

After endoscopic resection and X-ray therapy the average duration of life was about two years; after prostatectomy and X-ray therapy it was rather more than three years, but this group included more of the adenomatous type previously mentioned. With no treatment other than permanent suprapubic cystostomy the average was nine months.

Failure to respond.—If we now consider the 40 cases in which æstrogens have been used for four and three years the number who failed to respond was 3, or 7.5%. One of these lived three months, one five months, and one two years and three months, but the growth showed no sign of regression.

Duration of benefit.—The number alive at the end of each year is shown in Table I.

TABLE I.—ÆSTROGEN TREATMENT 1943 AND 1944: TOTAL 40

Alive after 1 year	..	35	87.5%	Alive after 3 years	..	19	47.5%
Alive after 2 years	..	29	72.5%	Alive after 4 years	..	6	15%

(Two cases are untraced after six weeks and two years respectively, and these are presumed to have died at those times.)

Percentages in such small numbers are scarcely justifiable, and it must be remembered that 16 of those in the three and four year groups are still alive. Analysis of the four-year group separately gives the following figures.

TABLE II.—ÆSTROGEN TREATMENT FOUR OR MORE YEARS: TOTAL 16

Alive (October 1947)	5	31%
----------------------	----	----	----	---	-----

Figures of four-year survivals before the use of æstrogens were given by Harnett (1944) for a total of 382 cases; 90% were dead after four years. They are plotted in graph 1 together with the present series of 40 cases to show the percentage dying at the end of each year. The use of stilbæstrol appears to give a significant increase

clinical grounds. Such treatment "in the dark" frequently delays the correction of benign prostatic obstruction and is apt to bring a valuable method into disrepute.

Dr. E. Boyland (*Chester Beatty Research Institute, The Royal Cancer Hospital (Free)*): At the present time workers on the chemotherapy of cancer are concerned with palliative drugs, which inhibit the growth and spread of tumours but do not destroy them. That these inhibiting agents are themselves carcinogens appears superficially as a remarkable paradox in our present knowledge of the subject. That ionizing radiations have beneficial effects in cancer and can induce cancer has been known for many years. Other examples of agents with the two actions include the oestrogens which are effective in treatment of cancer of the prostate and induce cancer of the mammary gland and other organs, urethane which controls chronic leukaemia and induces cancer of the lung in animals, and 4-dimethylaminostilbene which inhibits the growth of tumours and induces cancer at many different sites in animals.

The close relation between carcinogenesis and inhibition of growth and the use of carcinogens in chemotherapy means that the study of the mechanism of action of carcinogens has a twofold interest, first for its own sake, leading possibly to prevention of the disease, and secondly for the study of the inhibitory actions which might help in the discovery of new chemotherapeutic agents.

The determination of the optimum or even adequate dosage in cancer chemotherapy is difficult but most important. The dosage schedule is very critical in treatment with nitrogen mustard. When mice with spontaneous mammary tumours or with transplanted lymphosarcomata were treated with four daily doses of 0.1 mg. per kg. of tris (B-chloroethyl) amine hydrochloride no inhibition of growth or prolongation of life was produced. When the same drug, however, was given as a single dose of 0.4 mg. per kg., inhibition of growth and prolongation of life were observed.

A remarkable feature of the chloroethylamines is the similarity of their action to the action of ionizing radiations. This is seen in the effect on the nuclei where chromosome fragmentation and increased stickiness of chromosomes may result. Both chloroethylamines and radiations can cause vesication, nausea, vomiting, leucopenia and thrombocytopenia.

In clinical trials chloroethylamines have produced better palliative effects in cases of Hodgkin's disease and in bronchogenic carcinoma than in cases of other forms of carcinoma. Such preferential action is common among these agents, as shown in the use of oestrogens for prostatic cancer and urethane for leukaemia. A pessimistic view of chemotherapy of cancer is that cancer cells are so similar to normal cells that no agent differentiating between them will be found. But if a compound is effective against one type of tumour only, then it is less likely to damage other normal organs. Because of this specificity of action in the existing agents, a range of different types of animal tumours should be used in the search for new drugs. Each new compound might be tested against a variety of forms of malignant disease including leukaemia, cancer of the mammary gland, prostate, lung, stomach, liver and bone. One striking indication of the progress which has been made in the subject is that prolongation of life can often be used as the criterion of effectiveness. We have substances such as the chloroethylamines, urethane and aminostilbenes which will prolong life of cancerous animals, and such compounds can be used as standards against which new substances can be compared.

The most important aspect of dosage is that the prescribed œstrogen must be taken regularly and continuously for the rest of the man's life. This must be impressed upon him, and his doctor. I have only too frequently seen its discontinuance for some slight side-effect followed by a reactivation of the disease.

General management.—90% of patients with carcinoma of the prostate have some degree of urinary obstruction, and the sooner it is relieved the better the outlook. Whilst stilbæstrol will often give this relief the process is a slow one; and surgical treatment is preferable. The most useful form for this disease is endoscopic resection of the prostate which not only overcomes the urinary obstruction, but provides material for biopsy. I have found adjuvant surgical treatment necessary in 36 of these cases (Table III).

Metastases.—Metastases were present at some stage in more than half the cases (Table IV).

TABLE III.—ADJUVANT SURGICAL TREATMENT

Endoscopic resection ..	27
Prostatectomy ..	7
Diathermy excision ..	2

No operation ..	3
Total	40

TABLE IV.—40 CASES. METASTASES PRESENT IN 21

Ossæous ..	15
Lymphatic ..	5
Pulmonary ..	4
Other viscera ..	2

It is probable that pelvic lymphatics were invaded more frequently: Muir (1934) showed from autopsy findings that they occurred in 77% of cases.

Secondary deposits in bone provide a good picture of the regression of the growth under œstrogens. In the patient whose phosphatase curve is shown (graph 2) metastases around the left acetabulum and in the ischiopubic rami showed considerable regression after ten months and almost complete disappearance after two and a half years. The fractured neck of the right femur after eleven months was not through a secondary deposit, but after three and a quarter years an osteolytic deposit appeared near the right acetabulum. This has again regressed under X-ray treatment and increased dosage of stilbæstrol, and he is well and walking three years and ten months after starting treatment.

Metastases in the lungs may disappear more rapidly. I have seen them disappear in three cases and I look on their occurrence as an indication for increasing the dose of œstrogen and not necessarily as a sign of impending death.

Lymphatic metastases will also regress in some cases.

Side-effects.—Testicular atrophy and cessation of erections are inevitable sequelæ of treatment. Enlargement of the breasts (figs. 1 and 2) and pigmentation of the nipples and of any scars, and of the mid-scrotal line occur in most cases. When the dose can safely be reduced the pigmented epithelium desquamates leaving a more normal coloration. These side-effects must not be taken as an indication to stop treatment.

Summary.—Carcinoma of the prostate is a disease which takes a variable course according to its clinical type. Before the use of œstrogens, however, it could be said with some certainty that the appearance of metastases usually meant death within a few months. With œstrogens this is not so and some patients may live for four years even with metastases. The most striking results are therefore seen in the worst cases, but the greatest prolongation of life follows its use in cases which have not metastasized.

It remains a surgical complaint and some form of surgery is needed in the majority of cases to get the best results. This should include the provision of material for histological examination without which treatment is often carried out on inadequate

literature on the subject which has been well summarized by Rhodes (1947). Susceptibility has also been the subject of consideration by many writers. Vitamin and œstrogenic deficiencies have been postulated, but the subject is complicated, chiefly by the fact that while infection is widespread, frank clinical disease is rare. Indeed Casey (1946) believes that perhaps "98% of poliomyelitis is a mild, widespread, highly communicable disease of young children leaving no residual paralysis".

There has always been a reservoir of poliomyelitis infection in London with sporadic cases occurring throughout the year and a generalized rise in incidence during the early summer persisting to the late autumn. In the pre-1947 pattern the peak was normally reached about mid-September and most of the annual cases occurred between the beginning of July and the end of November. Such a "peak", however, merely implied three or four cases a week instead of one a fortnight.

In London in 1947, up to October 25, 908 notifications were received, more than had previously been received in the whole decade 1937-46, and far exceeding the previous highest annual total of 134 in 1938. From the national point of view the epidemic rise was first distinguishable in the week ended May 31, when the cases reported rose by one-half (21 against 14). In London there was an apparently local beginning confined largely to the south-eastern sector which was soon overwhelmed in significance by a general and simultaneous rise in incidence throughout the county which was far too widespread to be accounted for by reference to any local beginning. It is in fact a mere academic point as to where in London the "explosion" was touched off.

In the age-analysis of the cases up to October 25, 1947, it was demonstrated that, whereas in 1937-46 the disease attacked mostly children (78% of the 1937-46 cases were under 15), in 1947 the percentage was only 64. Sex incidence in the 1947 epidemic is shown in Table I.

TABLE I.—AGE AND SEX INCIDENCE

Age	Males	Females	Age	Males	Females	Male excess
0-14	350	234	0-	21	13	+ 9
15-34	122	147	1-	32	26	+ 6
35+	28	27	2-	3	29	+ .
			3-	23	20	+ 3
	500	408	4-	33	18	+15
			5-	32	27	+ 5
			6-	29	16	+13
			7-	25	16	+ 9
			8-	16	12	+ 4
			9-	28	10	+18
			10-12	52	36	+16
			13-14	25	11	+14
				350	234	+116

In a summary of 36,000 cases (mainly American) of all ages, the International Committee found in 1932 that the male to female ratio was 1.3 : 1. The comparative overall ratio in London was 1.23 : 1.

Table II compares the incidence in each Metropolitan Borough. Fig. 1 shows the geographical distribution of individual cases represented by spots on the map.

Several features emerge. The boroughs with a significantly higher-than-average notification rate are Chelsea, Shoreditch, Southwark, Bermondsey and Lewisham. The experience of Islington is noteworthy. Not only did this borough have a significantly lower-than-average incidence, but those cases which did occur were crowded towards the Shoreditch boundary.

The areas of high incidence are surrounded by boroughs in which the incidence was close to the average for London as a whole, and are those clearly marked out as "isolated" areas of high incidence. What possible reasons are there for these divergencies from the average for London as a whole? Possible suggestions are:

[November 25, 1947]

Acute Anterior Poliomyelitis in 1947 with Special Reference to London

By Sir ALLEN DALEY

Medical Officer of Health, London County Council

THE 1947 outbreak of poliomyelitis in England was by far the largest that this country has ever experienced. Epidemics have been common and widespread in North America, Scandinavia, Australasia, and, during the recent war, in the islands of Malta, Mauritius and St. Helena. These island outbreaks are of particular interest and we shall return to them later on.

My own interest in the subject was stimulated in 1927 when an outbreak occurred in the City of Hull of which I was then Medical Officer of Health (Daley, 1927). A similar outbreak had occurred the previous year in Leicester and another in the following year in Glasgow, but, apart from these, the country as a whole had been remarkably free. There was nothing of special note in Leicester, Hull or Glasgow in any of these years and why it should have spread there and nowhere else is one of the mysteries of epidemiology.

It is pertinent first of all to discuss the value of notifications as an index to the incidence of the disease. Some decry them as valueless because the vast majority of poliomyelitis infections are so mild that they pass unnoticed, whereas when there is a local scare these, and many other illnesses, are notified as poliomyelitis. This is a valid criticism, but it is clear that cases developing paralysis are never likely to escape notification, and that, judged by paralytic cases, epidemics have occurred, the stature of which can roughly be assessed by the notification rates. When the disease is receiving widespread publicity, comparisons of incidence in one part of the country and another on a basis of notifications are reasonably valid, for the factor of error is likely to be of a comparable order throughout.

Assuming, therefore, notifications to be a rough guide to incidence, the most interesting features in recent years here and in North America are (i) a shift in the age-incidence towards the older age-groups and (ii) an increase in the number of cases of the brain-stem type. It is stated that in Japan, among the native population, there are sporadic cases with occasional epidemics involving children under two years (Van Riper, 1947), but although Japanese adults rarely develop the disease, American adults in the Army of Occupation do so. Burnet (1945) believes that more people now reach adolescent or adult life without developing immunity because modern sanitation has reduced the likelihood of subclinical infection from alimentary sources in childhood. This theory receives support from the aforementioned island outbreaks where the standards of sanitation are not high. For whereas in Malta (Agius, 1945; Bernard, 1945; Debono, 1945; Seddon *et al.*, 1946) and Mauritius (McFarlan, 1946; McFarlan, Dick and Seddon, 1946) where the disease is endemic, the majority of cases occurred in children under 5 years, in St. Helena (Kauntze, 1946) where the disease was previously unknown, the children under 5 were little affected and most cases occurred in the age-group 10-25. All three epidemics are believed to have been introduced by the armed forces of the Allies. The adult is more likely to develop the brain-stem form than the infant, hence Burnet's theory would explain both the higher age-incidence and the increase in bulbar palsies.

The number of suggested vehicles of infection is legion, but modern opinion has narrowed the issue down to two—both deriving from the human case or carrier—droplet spread from the nasopharynx or spread from the excreta through the familiar mechanism of "fingers, food and flies". Space forbids a review of the immense

literature on the subject which has been well summarized by Rhodes (1947). Susceptibility has also been the subject of consideration by many writers. Vitamin and æstrogenic deficiencies have been postulated, but the subject is complicated, chiefly by the fact that while infection is widespread, frank clinical disease is rare. Indeed Casey (1946) believes that perhaps "98% of poliomyelitis is a mild, widespread, highly communicable disease of young children leaving no residual paralysis".

There has always been a reservoir of poliomyelitis infection in London with sporadic cases occurring throughout the year and a generalized rise in incidence during the early summer persisting to the late autumn. In the pre-1947 pattern the peak was normally reached about mid-September and most of the annual cases occurred between the beginning of July and the end of November. (a) *More complete notification or over-notification.*—Frank cases of paralysis can hardly have escaped notification anywhere. On the other hand many patients were admitted to hospital as suspected poliomyelitis in whom the diagnosis was not confirmed. For patients treated in L.C.C. hospitals up to the end of August the proportion not confirmed was 43% but there is no evidence that such errors of diagnosis were more common in one borough than another.

(b) *Social conditions.*—To test the relationship of incidence with social conditions an examination has been made of the correlation of poliomyelitis attack rate with the social index of the boroughs, i.e. the proportion of males aged 14+ who were in social groups IV and V (the lowest groups financially) at the 1931 census. No significant association was found.

(c) *Differences in immunity level.*—We know so little about this that it is impossible to say whether or not there were any differences between the different boroughs.

(d) *Differences in methods of control.*—The methods of control which were adopted are set out later. I have personal doubts as to the real efficacy of any of these, but they were applied in every borough and I do not think that any slight differences there may have been affected the borough incidence.

Examination of the borough statistics therefore throws no light on the epidemiological factors involved.

Age-incidence.—The notifications in London since 1921 have been analysed for incidence in children under 5. The figures are shown in Table III. Between 1921–23

LONDON: ADMINISTRATIVE COUNTY.

1946	39	14	35.9
1947	908	249	27.4

and 1936-38, the proportion of the total population in the under 5 age-group fell from 8.8% to 6.1%, subsequently rising to 7.3% in 1946. The fall in the infant population might account for some of the decline from 55.5% (in 1921-23) to 40.7% (in 1936-38) and 27.4% (in 1947) in the proportion of infantile cases of poliomyelitis, but that the decline should have persisted despite the reversal of the population trend suggests either that recently there has been an increase in the number of infants who have been immunized and are therefore insusceptible to attack with a corresponding increase in the unimmunized among those who are older, or that there has been some change in the virus to which the older age-groups are now more susceptible.

Housing conditions—Overcrowding: Out of 908 notifications there were only 27 instances covering 59 cases of more than one reportable case in the same building, i.e. the risk of a multiple case is 3%. This low risk indicates either that contact is not important, or that the rest of the family are immune, or, although the whole household is infected, in one only does the virus give rise to a clinical case. It is of interest to know the periods between infection in multiple cases.

Days:	0-2	3-5	6-8	9-11	12+
Occurrence:	15	1	2	4	10

Thus if we exclude the cases notified within a few days of each other, the number of true secondary cases is very small indeed. In 23 families or communities there were 2 cases; in three, there were 3 cases; and, in one instance, there were 4 cases. Space forbids discussion of the reasons for this, but there is some statistical evidence that true paralytic poliomyelitis is less common in overcrowded households.

Contact and exposure.—The contact and exposure history of a sample of 391 hospital cases is shown in Table IV but there is little or nothing to be learned from them and no controls by which the value of the figures might be assessed.

At school	—	Tooth extractions	2						
At work	7	Tonsillectomy	6						
No history of contact	351	Violent exercise	13						
<hr/> Total cases in series		<hr/> 391							

General epidemiological considerations.—Very few lessons have emerged from our analysis. We do not know why the disease was so much more prevalent in England in 1947 than ever before. Various theories, unsupported by facts, have been put forward. The hard winter, followed by a hot, dry summer, has been blamed. This as a causal factor, is pure surmise. Others relate the epidemic to poor nutrition, but poor nutrition cannot be the cause of the epidemics in the U.S.A. or Australia which are among the best-nourished nations in the world, and neither in those countries nor in this is there any evidence that the disease picks out the undernourished. Another theory is that a variant of the virus has been introduced by the returning troops and that it has broken through the resistance of those immune to the native virus. It may well be that there is something in this theory.

Authentic cases are reported of second attacks. This may be due to the immunity being short-lived or to attack by a different type of the virus. What is the explanation of the change in the age-incidence? Assuming (a) that immunity is, in the vast majority of cases, lasting, (b) that during the course of immunization only a very small proportion of those infected develop the clinical disease, and (c) that there has been no marked change in the type of the virus, the only theory which would account for the alteration in the age distribution would be that until a decade or so ago the vast majority of the population were infected in infancy by the nasopharyngeal or alimentary route. By assumption (b) the total number of clinical cases was small but the bulk of the cases occurred among infants. The patients in those years who developed the disease at a later age had escaped immunization in infancy. The rise in the age-incidence during recent years would point to a larger proportion of the population having failed to be immunized in infancy. This may have been due, as Burnet suggests, to improved sanitation, particularly in relation to food handling.

MEASURES OF CONTROL

Obviously in dealing with a disease, the natural history of which is so imperfectly known, the task of the Health Officer who is endeavouring to control it is not an easy one. In London this responsibility is shared between the boroughs, the City and the county. All my colleagues have kindly informed me of the steps they took locally, many of which were in response to public pressure rather than the result of scientific conviction. It was generally assumed that spread was from the nasopharynx or from the alimentary tract. We advised that the assembly of young people in crowded, badly ventilated, rooms should be avoided, though we wished to interfere as little as possible with the normal life of the community. Gargles and sprays were usually discountenanced. A few medical officers asked that special children's cinema *matinées* should be discontinued. If a case occurred in a day nursery it was closed—this happened only in 7 out of 130 nurseries. Operation for the removal of tonsils and adenoids was, by common consent, suspended except in urgent cases. Paddling pools which could not be chlorinated were drained. Chlorinated swimming baths were kept open, but many swimming galas, because of the violent exertion involved, were cancelled. Special steps were taken to reduce the fly nuisance by attention to refuse containers. Holiday camps for school children in this country were not prohibited, but it was considered inadvisable to send parties of children abroad. At only one camp did any trouble develop. This held 240 secondary school children and assembled on July 25. One case occurred which was sent to hospital and the party went home on August 9, on which day a new party of 168 moved in. Of these, three developed the disease, but from the history it was clear that they had brought the infection with them. This batch of children left on August 23 when a vigorous attack was made on the camp and its surroundings with Gammexane, D.D.T. emulsion, &c., during the three days before the next party arrived. Among the 61 who turned up no case occurred. Another interesting example was that of a residential nursery (outside London) of 125 children below the age of 5 years staffed by 80 persons: 6 young adult nursery trainees developed the disease, but only one of the children was affected.

The County Council was responsible for the hospitalization of cases, but its resources soon came to an end. The voluntary hospitals, especially the teaching hospitals, were asked to help, which they willingly did. Of some 900 patients admitted to hospital approximately half went to L.C.C. and half to voluntary hospitals. The supply of respirators threatened difficulties, but with the help of the King Edward's Hospital Fund sufficient for all needs were provided.

In the hope that it might throw some light on aetiology, on the means for the detection of early cases and on the need for long-term treatment, all hospitals concerned were asked to fill up a short questionnaire on the main features of the cases admitted. The first 391 cards returned have been analysed with the following result. They refer only to *confirmed* cases.

Table V shows the presenting signs and symptoms, the mental condition on admission and the result of the examination of the cerebrospinal fluid.

Table VI shows that 34.8% were abortive and 8.5% were cases of the bulbar type. From the point of view of preventive and social medicine the amount of residual paralysis is most important. Table VII shows that the case mortality was 5.1% and that 54.2% made a complete recovery. Table VIII divides the recovered cases according to the degree of severity of residual paralysis. There is a discrepancy with Table VII due to the fact that 11 of the 58 with "slight paralysis" were classed as "No (significant) paralysis" by the hospitals. In 28% of the genuine cases the attack was of the double-phase type giving a "dromedary" chart. In 6% of the total a respirator had to be used at some time or other. Overall, 25% of these 391 cases will probably have a limited working capacity and in 5% of the total this capacity will be almost nil. Table IX shows the distribution of the paralysis.

TABLE V.—HOSPITAL PATIENTS—PRESENTING SIGNS AND SYMPTOMS

Total Patients—391				
Symptom	No.	% of total patients		
Pyrexia	254	65.0		
Headache	265	67.8		
Vomiting	173	44.3		
Sore throat	75	19.2		
Stiff neck or back	257	65.7		
Constipation	51	13.0		
Abdominal pain	43	11.0		
Pains in limbs	181	46.3		
Paresis	101	25.8		
Paralysis	53	13.6		

Reflexes were diminished in 61.3 % of cases, normal in 33.0 % and exaggerated in 5.7 %.

* % of total cases in type group.

The normal procedure was to keep patients in the admitting hospital for about three weeks and then to transfer those needing special measures of rehabilitation to a long-stay suburban hospital where, in the case of children, education was available.

We may note here that the most common mistakes in diagnosis as revealed by an analysis of 71 unconfirmed cases out of 170 admissions to the Western Hospital under the care of Dr. Kelleher were as follows: Tonsillitis 10; rheumatism 5; cerebrospinal fever 3; lobar pneumonia 3; bronchitis 2; bronchopneumonia 1; tuberculous meningitis 2; cerebral tumour 1; cerebellar abscess 2; subarachnoid hæmorrhage 1; typhoid fever 1; measles 1; scarlet fever 1; chicken-pox 1; osteomyelitis 1; acute toxic polyneuritis 1; otitis media 1—a truly representative collection.

It has been a serious epidemic. Unfortunately, we have learnt little that is concrete about the epidemiology of the disease or its prevention, though certain trends observable elsewhere have been confirmed.

I must express to my colleagues, Dr. Scott, Dr. Breen and Mr. Benjamin, my very great indebtedness for help in compiling this paper and also the medical staff of a large number of hospitals, L.C.C. and voluntary, for the time and care they gave to filling up the questionnaire and finally I wish to thank the Medical Officers of Health of the City and the boroughs who have supplied much of the information as to local action which I have included.

Some Atypical Primary Tuberculous Lesions

By MARGARET MACPHERSON, M.D.

BEFORE describing atypical primary tuberculous lesions, I will first give a brief account of the accepted views about typical primary lesions.

In many urban districts about 80 to 90% of adolescents of 15 years of age have been infected by the tubercle bacillus according to the results of tuberculin testing.

After comparison of this with the morbidity figures for tuberculosis, it is obvious that the great majority of primary lesions are innocuous. Most children become infected during the school age. Fortunately it is at this time of life that primary infections appear to have little effect on the children and healing of primary lesions usually takes place, but it is difficult to say just how complete that healing is. Is there left any unhealed portion which remains as a potential source of tuberculous disease in later life?

In young children and infants primary infection more often causes trouble than in school children. At this age, children may develop gross tuberculous lesions in the lung with large areas of tuberculous bronchopneumonia, or there may be generalized tuberculous lesions, spread through the blood-stream, with miliary tuberculosis with or without meningitis.

In others, changes secondary to the primary lesion may develop, changes which in themselves are not tuberculous, such as areas of collapse of lung resulting from occlusion of a bronchus due to enlarged caseating lymph nodes. If the infant does not succumb to the primary lesion, it is usual for these lesions to recover completely. The capacity which a child shows for healing and calcifying these lesions is often surprising. But again the completeness of the healing and the relation of these lesions to disease in adult life are matters which cannot yet be determined conclusively.

Over 14 years of age, the picture of primary infection differs once more. Although many of the primary infections at this age are harmless, some appear to have a direct association with the type of active pulmonary tuberculosis usually associated with adult life. Observation of young adults during the period of conversion of negative to positive tuberculin tests, and for some years afterwards, tends to support this suggestion. I would stress "some years after" because there may be a latent period when there is certainly very little in the way of clinical signs or symptoms, and even X-ray appearances may change very slowly.

Having dismissed the problem of primary infection in school children as being of less interest and importance than in other ages, I now propose to describe five cases of primary lesions, in school children, which did not behave in the usual way.

There is sometimes a tendency to adopt the attitude that, so far as tuberculosis in children is concerned, the disease is either fatal or else it is trivial in its manifestations and therefore the clinician need not be greatly concerned about it. My object in picking out these five cases is to illustrate that primary lesions in childhood may show interesting and unsuspected changes if the lesions are observed carefully over a period of years by X-ray pictures. The changes show that the lesions at times are unstable and therefore should not be ignored in spite of the fact that they produce no clinical symptoms or signs. Moreover, cases such as these may throw some light on the ætiology of adult pulmonary tuberculosis.

The last two cases show that primary lesions are not always circumscribed and can develop directly into infiltration typical of chronic pulmonary tuberculosis. The last case also shows how slow and insidious this process can be, a steadily increasing infiltration being without clinical manifestations for a period of years. The first three cases show that what appears to be healed lesion is not necessarily so, and that reactions around calcified lesions can occur and do so after the lesion has been calcified for a considerable time. They raise the questions: what is the relation between these reactions and active pulmonary tuberculosis? were these children fortunate in arresting the disease? might they, in adverse circumstances, have developed chronic pulmonary tuberculosis?

CASE I.—J. C., aged 4 years 8 months.

Contact.—Sister of 9 years with acute pulmonary tuberculosis and positive sputum.

History.—Recent bronchopneumonia but no symptoms now.

Clinical picture.—Normal healthy child. X-ray showed a primary complex with enlarged hilar shadow on left side and small indefinite shadow left mid-zone (fig. 1). The primary lesion healed in the usual way, leaving a small calcified lesion in left mid-zone and calcification at the left hilum (fig. 2). Five years after the original X-ray, routine X-ray showed reaction round the calcified lung lesion (fig. 3). No symptoms or abnormal signs. This reaction subsided within a few months but left a residual small oval shadow associated with the calcified focus, which was unchanged five years later. The boy is now 18 years, healthy and in the R.A.F.

FIG. 1

FIG. 2

FIG. 3

CASE I: FIG. 1.—Primary complex with enlarged hilar shadow left side and indefinite shadow left mid-zone.

FIG. 2.—Calcified primary complex three years later.

FIG. 3.—Small reaction round calcified pulmonary lesion five years after first X-ray.

CASE II.—J. B., aged 4½ years.

Contact.—Mother and father died of pulmonary tuberculosis.

History.—No symptoms. Suffered from general debility from birth to 1 year old.

Clinical picture.—Normal healthy child. X-ray showed a large calcified lesion in right mid-zone, lateral view seen (fig. 4). Six months later said to have right-sided pneumonia, from which she recovered. Seen two months after this and X-ray showed reaction round the calcified lesion (fig. 5). Reaction subsided but at the same time calcified lesion decreased and disappeared. Fig. 6 shows lateral view, two years after the reaction developed, with no sign of previous calcification. Seven years later, at 14 years of age, X-ray is unchanged.

FIG. 4

FIG. 5

FIG. 6

CASE II: FIG. 4.—Lateral view to show calcified primary lesion.

FIG. 5.—Reaction round calcified lesion in right mid-zone, eight months later.

FIG. 6.—Lateral view two years after reaction developed, showing disappearance of calcified focus.

CASE III.—G. S., aged 10 years.

Contact.—Aunt slight.

History.—Recent anorexia, cough and pain right side of chest.

Clinical picture.—General condition poor. No abnormal signs. X-ray showed a large circumscribed opacity in the right upper zone with enlarged hilar shadow on right side, diagnosed primary complex. Healed in the usual way, leaving large calcified focus right upper zone and right hilum (fig. 7). Five years after the original lesion was found, when boy aged 15 years, area of reaction seen round calcified focus (fig. 8). No symptoms or signs at this time or subsequently. Opacity cleared after a few weeks, but calcified lesion much smaller and decreased considerably in size. X-ray at age of 23 years shown (fig. 9).

FIG. 7

FIG. 8

FIG. 9

CASE III: FIG. 7.—Calcified primary complex right lung.

FIG. 8.—Two years later, reaction in second and third spaces, round calcified focus.

FIG. 9.—Reaction subsided and area of calcification decreased.

The next two cases show atypical reactions to the initial infection.

CASE IV.—A. R., aged 10 years.

Contact.—Lodger, ill recently with pulmonary tuberculosis.

History.—Recent pyrexial attack of unexplained cause. Well when first seen.

Clinical picture.—Healthy child. No abnormal signs. X-ray showed left hilar shadow enlarged, and flocculent shadow left upper zone (fig. 10). After initial increase in shadow (fig. 11) it slowly decreased, becoming localized to small lesion one year later (fig. 12), subsequently showing only a small calcified focus in left upper zone and in left hilum. Girl now 21 years, in good health and X-ray unchanged for five years.

FIG. 10

FIG. 11

FIG. 12

CASE IV: FIG. 10.—Primary complex with enlarged left hilar shadow and diffuse lesion left second and third spaces.

FIG. 11.—Four weeks later. Increased flocculent shadow left lung.

FIG. 12.—One year later, calcified lesion left hilum and small localized lesion left second space.

CASE V.—S. G., aged 12 years.

Contact.—None.

History.—Recent cough. Attended hospital. No abnormal clinical or X-ray signs. Mantoux O.T. 1/100 negative. Was asked to attend two years later so that Mantoux test might be repeated for research purposes. Found to have Mantoux 1 : 10,000 positive and X-ray showed flocculent shadow right upper zone (fig. 13). Has been kept under supervision for seventeen years. During first nine years has shown slow progression of disease through right upper lobe and spread to left apex, and at same time healing of early lesions (fig. 14). First symptom was slight transient hæmoptysis five years after first positive X-ray (fig. 15). Fig. 16 shows further healing of right apex but spread to left side. Nine months later she had pain right side, fever and lassitude, and X-ray showed cavity at right apex (fig. 17). After sanatorium treatment cavity disappeared and there was retrogression of the lesion from that time. Fig. 18 shows state of lung five years later. From this time there has been little change and the girl is well and due to be delivered of her second child in three months' time.

FIG. 13

FIG. 14

FIG. 15

CASE V: FIG. 13.—Primary lesion with flocculent shadow right second space.

FIG. 14.—Three years later, shows diminution of original lesion but increased infiltration above.

FIG. 15.—Five years later, increased lesion right apex.

FIG. 16

FIG. 17

FIG. 18

CASE V: FIG. 16.—Seven years later, right apical lesion less but infiltration seen left apex.

FIG. 17.—Seven years and nine months later, cavity at right apex.

FIG. 18.—Twelve years later (aged 26). Lesions decreased and now stationary.

Section of Ophthalmology

President—HAROLD LEVY, F.R.C.S.

[October 9, 1947]

Leucosarcoma of Iris (Unpigmented Malignant Melanoma).—T. H. WHITTINGTON, M.D.

Married woman aged 64.

No history of past injury, or of inflammation, or of recent illness. Present history: one attack of acute pain in left eye on September 15, 1946.

On examination four days later a hæmorrhagic yellowish, lobed nodule was seen protruding from anterior surface of iris. Small hyphæma and blood clot which appeared to have come from the tumour cleared in five days. Vision 6/9.

Investigations.—On examination, nothing abnormal was found.

Diagnosis.—The growth in the eye does not appear to be cystic, and does not transilluminate; it does not appear to be tubercular or syphilitic, and there is an almost total absence of inflammatory reaction. It might be an encysted foreign body with fibrosis around but there is no history or sign of penetration. It is probably a new growth. Isolated new growths of the iris, i.e. not associated with growths of the ciliary body or elsewhere in the eye, are rare. Martin-Jones (1946) mentions only 4 cases of isolated sarcoma of the iris out of 263 cases of uveal sarcomata; one of these 4 had a spontaneous hyphæma, but all 4 were clinically pigmented. A clinically unpigmented growth is very rare. Duke-Elder and Stallard (1930) described a case and were able to collect only 25 other cases from the literature. Spontaneous hyphæma is also rare. Wood and Pusey (1902), in a review of 64 cases of sarcoma of the iris, state "an interesting symptom, which has been observed in these cases is recurrent hæmorrhage into the anterior chamber. Such bleedings tend to occur spontaneously, and have several times been the cause of sending patients to the doctor".

Treatment.—Operation on October 12. A corneo-scleral stitch—as used in cataract extractions—was put in at the margin of the cornea and a large conjunctival flap turned back; a scratch-through incision was made with a Graefe knife, extending from 1 o'clock to 5 o'clock. Then the corneal side of the wound with the stitch was lifted up and a very large basal iridectomy from 1 o'clock to 5 o'clock was made. After roughening the corneal epithelium at the edge, the conjunctival flap was slipped over the wound.

Histology (Dr. L. Woodhouse Price).—"Malignant melanoma. Morphologically the component cells are of spindle form and arranged in whorls. Intracellular pigment is fairly copious and is seen both in the tumour cells and in histiocytes or chromatophores. In the former, the pigment granules are of delicate form and of golden-brown colour. In the latter, on the other hand, the pigment assumes the form of coarse granules of dark-brown or black appearance. The presence of iron pigment was excluded by the application of the Prussian blue staining reaction. Moreover, the presence of the melanin was proved by intensification of blackness by ammoniacal silver solution. Ontogenetically this tumour arose from a nerve end organ. Enucleation of the eye is indicated."

On December 3, 1946, patient had quiet eye, vision 6/9. In view of the spindle-celled character of the tumour with scanty mitoses, and the fact that it seems to have been removed completely, and that iridectomy has been reported as successful in similar cases, the eye has not been removed.

- DUKE-ELDER, S., and STALLARD, H. B. (1930) *Brit. J. Ophthalm.*, **14**, 158.
 MARTIN-JONES, J. D. (1946) Uveal Sarcomata, *Brit. J. Ophthalm.*, Monograph Suppl., **11**.
 WOOD, C. A., and PUSEY, B. (1902) *Arch. Ophthalm.*, **31**, 323.

Mr. Williamson-Noble suggested one point in treatment, namely, to have some human thrombin put in the anterior chamber first. This might prove very helpful.

Mr. H. B. Stallard said that malignant melanoma of the iris showed no histological evidence of karyokinesis and so were relatively slowly growing. They are radio-resistant. The prognosis is good after removal of the growth with the adjacent iris. Excision of the eye for a nodular malignant melanoma of the iris not infiltrating the filtration angle nor touching the cornea was quite unjustifiable.

He described the case of a girl, aged 16, who had a malignant melanoma of the iris in 1931 and was treated unsuccessfully by unscreened radium. The neoplasm was removed by iridectomy. Histological examination showed no evidence of effective irradiation. The patient is still alive and well sixteen years after operation and has shown no signs of recurrence nor of metastases.

Melanosis of Conjunctiva.—A. S. PHILPS, F.R.C.S.

Mr. Philps said that this was a case of a lady aged 45, who for the past five years had had an increasing melanosis of the conjunctiva of the left eye (figs. 1 and 2). Lately the pigment had invaded the cornea as well though none appeared intra-ocularly. Vision in this eye was 6/6. A piece of conjunctiva had been excised and sections of it were shown.

FIG. 1

FIG. 2

FIGS. 1 and 2.—Melanosis of the conjunctiva present for five years and increasing slowly. The patient uses no eye drops of any kind.

Mr. Eugene Wolff said that the point of interest was that the section showed an ordinary nevus—a mass of nevus cells almost without any cytoplasm—and around this downgrowths of pigmented epithelial cells. This was very unusual in melanosis. Some sections showed the cells proliferating and revealing early malignant changes.

Mr. G. T. W. Cashell said that he had described to the Section in 1940 (*Proc. R. Soc. Med.*, **33**, 545) a case of an old lady aged 70. He had excised a small tumour of the limbus; on section it showed malignant melanoma and he had exenterated the orbit.

This condition was described by Reese (*Arch. Ophthalm.*, 1938, **19**, 354) when he mentioned 8 cases of what he called precancerous melanosis of the conjunctiva. Reese had suggested that these cases should be watched very carefully. The onset of malignant change was usually accompanied by a severe inflammatory reaction in the eye, and that was the time to exenterate the orbit.

The President said that it had struck him that this pigment was distributed all over the local area, but there was no sign, as far as he could see, of any growth. Of course, if it was found that there were malignant cells, this made the treatment more obvious than it would otherwise be.

Hereditary Hæmorrhagic Telangiectasia with Conjunctival Lesions.—Major HOWARD REED, R.A.M.C.

This patient, aged 19, complained of excessive blinking, a feeling of "something in the eyes", and he had frequent epistaxes. His mother, when she was alive, suffered from frequent nose-bleeds, and a younger brother has had several epistaxes. Telangiectases were present on the palpebral conjunctivæ, nasal mucosa, tongue, buccal mucosa, and skin (figs. 1 and 2). No miliary aneurysms or other lesions could be seen in the fundi and the blood-count was normal.

FIG. 1

FIG. 2

ALEXANDER

Everted upper lid of right eye to show conjunctival lesions in case of hereditary hæmorrhagic telangiectasia. FIG. 1.—Slit-lamp appearance of telangiectasis. FIG. 2.—Macroscopic appearance of telangiectases.

The salient features of the disease were described by Osler as hereditary hæmorrhagic telangiectasia, with several family trees which showed a dominant inheritance with equal sex distribution. The condition usually becomes apparent soon after adolescence by recurrent attacks of bleeding from the nose. Hæmatemesis, hæmoptysis, hæmaturia, and even cerebral hæmorrhage have been described in association with this condition.

Appreciation of Form and Colour after Cataract Operation.

Mr. F. A. WILLIAMSON-NOBLE exhibited two landscape paintings executed by a patient, one before and the other after operation for cataract. He said that various differences were perceptible between the two renderings, especially in the colouring and detail of the skies. The clouds, for example, were seen much more clearly after the operation. What was most remarkable was the difference in the size of objects. The post-operative landscape was definitely smaller in scale than the pre-operative one, and that tallied with experience of other patients after cataract operation—the 6/6 line was equivalent in size to about the 6/9 line in the case of someone who had not undergone the operation.

Stereoscopic Pictures.—Mr. F. A. WILLIAMSON-NOBLE also showed a new method of stereoscopic photography which, he said, was likely to be of value in ophthalmic work. He had been loaned ten pictures by the Austin Motors Corporation, who had been using the method. Two devices are used—one for photographing small subjects at not more than 10 ft. (3.05 m.) distance—is a camera which travels in an arc and 24 pictures are taken in ten seconds. For larger pictures a 24-lens camera is used, the lenses being disposed in two horizontal lines each of twelve. The combined print is covered with a fine optical grid which ensured a selective view by the two eyes.

Considerations on the Treatment of Detachment of the Retina¹

By Professor H. ARRUGA (Barcelona)

AFTER Gonin's publication of the results obtained by his operation for detachment of the retina, those of us who practised this operation at the time were successful only in about 25% of cases. The perfecting of technique has caused this percentage to rise to as much as 70 or 80, taking into account all operated cases indiscriminately. This percentage of cures, attained in the last six or eight years, cannot easily be exceeded in spite of our increased experience.

Of the 20% or 30% of patients on whom we operate but cannot cure, we know beforehand that about half are unlikely to be successful, either because of the difficulties they present (very large or multiple rents, opacities in the media, subjects with systemic disease, &c.) or because of the age of the lesion; but, in the other half of that 20% or 30% of uncured cases, we had hoped to effect cures because we had succeeded in other similar cases, and our failure is due to abnormal developments in the curative process.

In my experience there is no type of detachment in which 100% of cures is obtained. The only cases in which I have obtained cures without complications are those in which I have diathermized rents without detachment or with a hardly perceptible detachment, that is, cases in which the retina had not yet detached, and the edges of the rent did not show any appreciable unevenness when examined through the ophthalmoscope. In such cases even a slight diathermic application is observed at once by ophthalmoscopic examination owing to the coagulation of the retina. In these cases the early symptoms of floating opacities or hæmorrhages into the vitreous led the patients to consult an oculist and so facilitated the discovery of a recent rent, the rupture of whose vessels provoked the hæmorrhage in question. In most of these cases there had already been a detachment of the retina in the other eye (and the patient's sharpened observation of these symptoms has made early treatment of the retinal rent possible). I have operated on 23 cases of this type of recent rent without detachment with perfect results and without any loss of visual acuity; of course, in none of them was the perforation situated at the macula. I have also invariably had perfect results in diathermizing areas of intense vacuolar degeneration of the retina without detachment. This type of retinal degeneration is frequent in the supero-external area parallel to the equator, and in cases where there has already been a detachment of the retina in one eye, diathermy of the degenerated area in the other eye can legitimately be practised. As an extra precaution in such cases, I have used a low current, just enough to coagulate the retina slightly. I start with a very weak current and increase its intensity until the coagulation of the retina is obtained. The intensity of the current varies in each case, but sometimes currents of as little as 10 to 15 milliamperes are effective.

Detachments of a favourable anatomicopathological type which run an unfavourable course.—Apart from the cases in which there is only slight or no detachment of the retina, there is always a possibility of complications, even in the simplest cases. For instance, I have had occasion to operate on cases in which detachment was reduced by bandaging and rest for six days, at the end of which it had almost disappeared. In these conditions, I operated on the patient with surface diathermy, and at the end I was convinced that he would get cured, yet the development of the disease was unfavourable. The patient developed slight pains and photopsiæ. In spite of further rest and the institution of treatment including penicillin, on the remote chance of there being some infection, the condition of the eye did not improve. The area around the rent appeared turbid and the detachment spread in all directions.

¹Dr. Arruga illustrated his talk to the Section with numerous pictures.

The only explanation I can offer is that the choroid was in a peculiarly sensitive condition, owing to the existence of a chronic inflammatory process, so that the action of the diathermy was intensified.

I cannot see how such an unfavourable development could be foreseen in a case which was apparently so easy to cure. Only when a patient presents a local reaction or has any pain, or when the vitreous is turbid round the rent, without the turbidity being due to blood, can we suspect that the choroid is inflamed or likely to become excessively inflamed by diathermy.

This excessive reaction is observed more frequently in certain patients who have been operated on previously; and this led Weve to think that such cases were anaphylactic. I believe the irritability of the choroid is due to the fact that it has been inflamed previously, and that this inflammation had not disappeared at the time of the second intervention.

Detachment starting at the macula.—In a detachment at the macula, the rent is very small and is very difficult to cure. Although this is the type of rent whose start is soonest noticed by the patient since it affects central vision, the rest cure does not improve it as it does most detachments with small rents when the patient is made to rest in bed with the eyes bandaged.

These rents at the macula are not increased by movement, as are all other types, probably because macular rents are not caused by traction of the vitreous on the retina by means of adhesions between its framework and this membrane, but by choroidal exudation which pushes the retina towards the centre of the eyeball and tears it circularly near the centre of the macula, where it is very thin.

The retina in the macular area is more adherent to the choroid than elsewhere except at the ora serrata where adhesion is even firmer. It is due to this mechanism of the formation of macular rents that they are round and have no floating shred such as round rents have in other retinal areas; here the shred remains adhered to the choroid.

The fact that sometimes the macular rent is secondary, for example, that it may occur when a detachment initiated by one or more rents in another area reaches the macular area, confirms this mechanical process, its production by the retina being pushed into the cavity of the eye by subretinal fluid.

The pathogenesis of detachments of the retina starting with macular rents raises a therapeutic problem necessitating care in applying diathermy (as is indeed always necessary in view of the functional importance of this area); moreover, the subretinal fluid should be drained through a sclero-choroidal puncture at some distance from the central area and in the lower part of the globe, where the detachment is usually greatest.

Detachment of the ora serrata.—One of the features of this kind of detachment is the small influence of rest. The retina never becomes reattached in its original position, even as a result of a successful operation. Success can only consist in getting the retina joined to the choroid throughout the sector which borders the retinal aperture.

As a result of this condition the retina does not become adapted to the choroid by rest, even when punctures are made during the operation to drain off the subretinal fluid at the level of the disinsertion. In these punctures we do not obtain a fluid which is progressively yellower with the age of the detachment, as occurs in the other types of detachment; what we get is a liquid of a viscosity similar to that of the vitreous.

The reason why the retina cannot be adapted to the choroid in cases of disinsertion at the ora serrata is probably that the retina is affected with an inflammatory or degenerative process, either of which is followed in its natural development by atrophy and retraction of the retinal tissue proper.

As a consequence of this the retina must be diathermized at the point where it still touches the choroid, or is very close to it. We have to try to verify with the ophthalmoscope whether the retina is coagulated with a characteristic whitish colour if we are to expect a cure, and this is often not obtained unless we diathermize near the posterior pole; but we have to sacrifice some peripheral visual field in order to preserve the central visual field and cure the disease by strictly limiting the detached area.

It is useless, and often harmful, to diathermize the retina in the peripheral part where reattachment is not possible.

The following case was unusual both by its gravity and by the fortunate cure already described in my first book on detachment of the retina.

This was a patient who was blind in the right eye owing to an old detachment and whose left eye showed a detachment. In an attempt to improve the local condition by rest, she was put to bed with a binocular bandage. After a month there was no improvement. The patient was operated on by diathermy applied over the entire vertical meridian, passing behind the optic nerve on its internal part. Fortunately, the detachment was restricted thereby and, at the end of a year, the patient had 0.2 vision in that eye.

It is curious to note that the choroid, which still had the characteristic red colour at the end of a year, five years later—that is, six years after the start of the disease—was totally atrophied, and the detached retina was almost transparent and bloodless, its vessels having almost disappeared.

This atrophy of the choroid is verified histologically in all the microscopic preparations of enucleated eyes where there had been an old detachment of the retina, a fact which proves that the vitreous is not tolerated by the choroid. This explains why, in some detachments, this intolerance of the choroid to the vitreous asserts itself by uveal reaction (turbid vitreous, a poorly reacting pupil, ciliary injection), which is certainly unfavourable for the progress of the disease.

Inferior detachment.—This kind of detachment also has an anomalous development owing chiefly to the fact that it may go on for some time without being noticed by the patient. This development is due to the subretinal fluid occupying the inferior region of the eyeball, where, owing to natural development and to its weight being greater than that of the vitreous, the fluid is displaced in all cases of detachment; this makes the progress of detachment slower when it starts in the lower part of the globe.

On the other hand, the reduction of the field of vision caused by the detached area of the retina is not readily noticed by the patient, because it occurs in the upper part which is already much reduced by the superciliary arch; indeed it is not clearly perceived until it reaches 55° or 60° in the vertical meridian, corresponding to about 14 mm. distance from the corneal limbus, a little behind the equator.

Consequently when we see a detachment of the retina restricted to the lower part, either with a disinsertion or with rents near the inferior pole, it is difficult to know when exactly it started. Patients can help us if they have noticed photopsiæ or floating opacities in the vitreous; but we frequently can form no accurate estimate of the age of the lesion. Sometimes the patient has noticed it only for a few days, and on examining him with the ophthalmoscope we see unmistakable signs that the detachment is old: for instance, folds in the retina and pigmented lines, which lead us to infer that the lesion is months, or even years, old.

If the detachment is recent, diathermy of the torn areas is the best technique; but if it is old, this is useless, since a choroid that has been in contact with the vitreous for some time cannot possibly react. In such cases, we must be content with limiting the area of detachment by means of a barrier of retino-choroid adhesions, similar to that which is made in cases of disinsertion in the ora serrata.

In some of these cases, the detached portion, although well-defined and limited, produces symptoms which are a continual source of alarm to sensitive patients. These may be photopsiæ, and floating opacities (*muscæ volitantes*), which are inevitable if any part of the retina is detached and moves with the movements of the eyeball. If the patients are good observers, they realize that the photopsiæ are confined to the area of the detachment whereas the floating opacities extend beyond it. If the photopsiæ go beyond the detached area, we must examine the field of vision to verify whether the detachment is spreading; this can also be seen by ophthalmoscopic examination as a slight opalescence of the retina, similar to that found in œdema of the retina. If there is such spreading of the detachment, we must apply diathermy slightly in the affected area.

Sometimes the well-defined area of the retina shows an accentuated bulge which remains the same for many years. At first such cases worried me a great deal as I feared relapses, but fortunately when the union between the choroid and the retina is firm, they do not relapse.

And thus I end this *exposé* of these aspects of the treatment of detachment of the retina. The subject is indeed a complicated one, owing to the great diversity of clinical types and, consequently, of techniques to be followed.

In conclusion, I cannot fail to pay tribute to our master Gonin to whom we owe it that one of the diseases in ophthalmology which was always thought to be incurable can now be cured in most cases.

Sir Stewart Duke-Elder congratulated Professor Arruga warmly on his lecture, saying that there was no one in the world who spoke with greater authority on this subject. The fact that 70% or 80% of successes had been recorded in a series of cases of this type was due to no one alive more than to Professor Arruga himself. There were one or two things which were (to the speaker) extraordinarily interesting. For example, there were the cases in which the retina showed a small hole readily accessible and presenting every appearance favourable for treatment, but which nevertheless did not do well at all. He himself had had a case of this type about two months ago. He thought at the time that the unfavourable result of the operation might have been due to excessive reaction. The case showed a small hæmorrhage in the retina some distance away from the hole, but the only result of operation was to convert the single hæmorrhage into several and a partial detachment into a total one. Such a result was quite possibly due to the exacerbation of a pre-existing pathological condition of the choroid making it react in an unusual way to diathermy. Another point of interest was Professor Arruga's technique of the adaptation of the procedure at operation to the age of the lesion, diathermy over the torn areas being practised if the detachment was recent, whereas if it was old, the best procedure was to diathermize round about it to limit the area of detachment by means of a barrier of retino-choroidal adhesions.

The author had given them not only an exposition of the general subject, but had added those personal touches from his own practice which only an expert of great experience could give. He wished to comment in particular upon the excellence of his illustrations. Professor Arruga made all his drawings himself by a technique which he had worked out, not painting them in the usual way but by using a spray and stippling. The results were excellent and added greatly to the value of his exposition.

Mr. Humphrey Neame said that he desired to bring to Dr. Arruga's notice an illustration of a retractor modelled on his own retractor but made of a plastic material for carrying and projecting the light. Some of the reflected light reached the terminal part of this material and this was distributed over the surface of the eye. His instrument, which had been made about four years ago, illuminated the area very well in addition to its giving one a view down the tunnel of the speculum. This had been reproduced in the *British Journal of Ophthalmology* (1943), 27, 310. A new modification was a 6-volt bulb, which was considerably better than the bulb of weaker intensity previously used. In dealing with the upper or lower parts of the field it was better to remove the eyelid speculum and view with this instrument alone.

Mr. A. S. Philips said that to find that the detachment had increased after operation was probably something that had happened to all of them. He personally would have thought it due to a thrombosis in the major branch of one of the vortex veins, or perhaps the vortex vein itself. If such a thing happened it might be that the back pressure caused exudation and the separation of the retina to a greater extent than before operation. He had explained this by saying that where it so happened it was because of too much reaction which had brought about thrombosis in the choroidal vein or perhaps the main trunk of the vortex vein itself.

Mr. G. W. Black said that he had been most impressed by the boldness shown by Dr. Arruga in tackling holes with no associated complications and in the treatment by diathermy of areas of retinal degeneration, thought liable to be the starting point of detachment. Did Dr. Arruga never hold his hand? He recalled his own experience that roughly 7% of cases spontaneously recovered following a period of rest without recurrence of the detachment and that such cases might show tears in the beginning or might not. In some bilateral cases, one eye might recover and never need surgical treatment, whereas the other required operation. Did the author not think that the presence of a detachment in some cases caused a mildly irritant reaction which offered some possibility of natural cure?

Dr. Arruga, in reply, spoke of the importance of dealing with tension as part of the cure. If he had a large separation and the patient showed no signs of getting better with rest he would carry out a puncture in the sclera and choroid, but in his experience this had not been very satisfactory, and in fact he had had a number of bad results with puncture before operation. As for detachment in the aphakic eye, he said humorously that he would be able to answer that question in thirty years' time. He had experienced more detachment with intracapsular than with extracapsular extraction—he did not know why. He could affirm that detachment was not the consequence of operation, but the consequence of the lesion in the retina.

Dr. Arruga found some difficulty in making himself understood in English, and spoke in French and was interpreted by the President (Mr. Levy) from this point. He said that in all detachments they knew that there were two processes by which this could be caused: (1) retraction of the vitreous and (2) the pushing forward of the retina by the choroid, the retina itself remaining passive. In any given case it was not known exactly which of these two processes might be operating. In detachment the curative organ was the choroid. This was the vascular organ of the eye and could absorb the subretinal fluid. Therefore if there was any atrophy of the choroid absorption was not possible and a cure could not be obtained. The exudative power of the choroid was also important because upon this depended the formation of adhesions between the retina and the choroid. Therefore it was important that neither the absorptive nor the exudative power of the choroid should be destroyed, and treatment must be directed as far as possible to avert such destruction. The operative interference must be sufficient to produce exudate and to seal down the detached retina at the same time leaving sufficient undamaged choroid to absorb the subretinal fluid. Unfortunately the state of the choroid before operation was not known. It was to be hoped that an investigation of this problem might be carried out in the future.

As a result of observations made some years ago it was known that the retina did not detach (except as the result of accident) unless diseased and that the actions of the retina and choroid were interdependent.

The President thanked Dr. Arruga in the name of the Section for his interesting paper.

Section of Urology

[October 23, 1947]

Modern Trends in Prostatic Surgery. [Abridged]

PRESIDENT'S ADDRESS

By WALTER W. GALBRAITH, M.B., F.R.F.P.S.

SIR PETER FREYER was the first President of this Section of the Royal Society of Medicine (1920) and it is to him more than to anyone that we owe the earliest successful form of treatment for prostatic obstruction.

Freyer's operation held the field in Britain for twenty-five years. It was the operation of choice for the general surgeon but few achieved results comparable with those reported by Freyer (1901-09-11). Haemorrhage and sepsis, at and following operation, and later obstruction, were common and generally the mortality rate was high.

In an endeavour to improve on the Freyer operation Thomson-Walker (1920) introduced an operation whereby an effort was made to control the bleeding at the operation, to lessen sepsis and to prevent post-operative recurrence of obstruction. Although in skilled hands it resulted in a diminished mortality and a greater freedom from complications this operation proved too complex for the average general surgeon, who continued to use the much simpler Freyer method.

About 1930 the treatment of prostatic obstruction was still unsatisfactory and the mortality in general hospitals was estimated to be about 20% although in special hospitals, such as St. Peter's, it was reported as 9.9% over a twenty-nine-year period but fluctuated in different years from under 5% to 14.5% (Thomson-Walker, 1936). From that time all our efforts have been directed to improving pre-operative, operative and post-operative methods in the hope that the incidence of mortality and morbidity might be lessened not only in a few special clinics but generally throughout the country. We are still, however, seeking a method which is simple, safe and sound. Some success has been achieved and to-day results generally show a definite improvement on those of twenty years ago. There is still, however, considerable divergence of opinion regarding the selection of operative procedure in the treatment of prostatic obstruction. Urologists should be thoroughly familiar with the various techniques: they can then adopt the method which they consider most suited to the patient, to their own skill, and to the particular circumstances.

I will now review the methods of treatment in vogue to-day and the conclusions concerning them at which I have arrived as a result of twenty-five years of urological practice.

(1) *The Freyer operation.*—This remains the most commonly practised method of prostatectomy among general surgeons, who frequently refer to the good results they have achieved with it. Whilst this may be so on occasion, on the average the post-operative discomfort, the long convalescence and the end-result surely indicate the undesirability of such a technique except where the poor physical condition of the patient necessitates a very short operation. Where a thirty- or forty-minute operation cannot be contemplated and in certain other cases governed by special factors, the Freyer operation, or rather its present modification, is of value. By "modification" I mean a moderate-sized incision, a quick and clean enucleation of the gland, adequate control of bleeding by a suitably sized Foley indwelling urethral catheter and closure of the bladder wall around a small or medium-sized Freyer drainage tube. This tube should be removed whenever the possibility of clotting is over, say in twenty-four hours, and after a further twenty-four hours the Foley catheter should be replaced by an indwelling No. 22 F size urethral catheter. These measures generally obviate the use of the suprapubic box. The wound heals rapidly, fistula formation is less likely or of short duration, and removal of the catheter on the tenth day generally ushers in natural micturition. I have found this the operation of choice in approximately 10% of my cases.

(2) *The Thomson-Walker operation.*—This improvement on the Freyer operation was first popularized by the late Sir John Thomson-Walker (1920, 1936). Since the advent of the closure operations I have ceased to use the Thomson-Walker operation and I see no useful place for it to-day.

(3) *Per-urethral resection*.—This method, in its present form, originated in America about 1930 and soon was acclaimed as the ideal treatment for all forms of prostatic hyperplasia. Not only were members of the medical profession swept off their feet by a wave of enthusiasm but the general public, having heard of the new method which obviated a "cutting operation", demanded it. Few now make use of it for every prostatic hypertrophy; most reserve it for the treatment of fibrous glands, the small subcervical adenomata and the case of obstructing carcinoma with impending or actual retention. In America the Mayo Clinic use it in preference to any other form of treatment and Emmett (1944) reports that for the ten-year period preceding 1942, 9,000 resections were performed there with a mortality rate of 1.1% and an average hospital stay of 8.6 days, only 3% requiring further resection at a later period for recurrence of obstruction. In England, Wardill (1947) also uses this method exclusively. He states that his cases are entirely unselected and that he has performed 537 resections during the twenty months prior to August 1947. 26 patients died (4.84%) and 58 required more than one resection (10.8%). On the other hand Millin (1946) after performing 219 resections discarded it, on account of late complications, except in the type of case I have specified. Chapman (1947) states that till recently he employed the method exclusively except for certain bad risk cases which were treated by permanent suprapubic drainage. He reports 379 cases with 24 deaths (6.3%). His present practice is to treat the large adenomatous prostate by suprapubic prostatectomy and 20% of his patients are now so treated.

There are two different methods of performing this operation: (1) by the McCarthy instrument using a cutting loop activated by diathermy electric current to excise the tissue, and (2) by the cold punch instrument, known as the Thompson resectoscope or punch, by which tissue is removed by a circular knife. The McCarthy instrument was first in the field and I gave it an extensive trial. Although of large size the shaft of the instrument required little movement in the urethra during the operation and thus I found the incidence of post-operative stricture was less than when using the punch instrument; its disadvantages were that the lens system, becoming clouded by blood, reduced visibility and made it difficult not only to recognize anatomical landmarks but to resect sufficient tissue and furthermore the operation tended to be prolonged as after each cut the telescope and cutting loop had to be withdrawn with the attached piece of tissue. I discarded the method when I acquired a Thompson punch which I found much simpler to use in that it permitted good visualization despite appreciable hæmorrhage and thus one was able to remove a large amount of tissue in a comparatively short time.

I have performed per-urethral resection on 26% of my cases and that includes a period of one year during which, to gain experience, I used the method almost exclusively: the results are shown in Table I.

TABLE I

Type of patient	Number	Died	Mortality percentage
Private..	69	7	10.14
Hospital	86	8	9.3
Total	155	15	9.6

My reaction to the operation, using the cold punch, is that I dislike the large size of the instrument which is stated to be size 30 F but which actually is often size 32 F and thus too large for the normal urethra. A smaller instrument is made but it is much less effective and seldom used. Many of my cases developed severe urethral stricture as a result of the passage of the large instrument. How could it be otherwise when one considers the tightly fitting instrument in the urethra with its constant piston-like movement against the delicate urethral mucosa? It is true that stricture formation can be partially obviated by inserting the instrument through a urethrotomy opening in the bulb but most of us would hesitate to perform this additional, even temporary, mutilation. A further difficulty I found with the instrument was in determining when a sufficiency of tissue had been resected. Time and again I considered that I had removed all obstructing tissue only to find a few days later that the patient still had difficulty in micturating freely or even that retention was still present. A further resection was then carried out and indeed at times resection was necessary on three separate occasions. I believe that this is not an uncommon occurrence but I am willing to admit to some inexperience. Presuming a man to be an ordinary skilled instrumentalist how many resections should be necessary before he could expect to achieve reasonable perfection? I have heard various estimates of from one hundred to three hundred but that seems an immensity of suffering to inflict in the pursuit of even a moderate degree of skill by this method! But there are other defects and the most important of these are hæmorrhage and sepsis. The operation cannot be performed without very considerable blood loss which starts with the first cut and is continued for several hours following it. The blood loss can be made good by transfusion although that is only necessary in a few cases but to prevent

clot retention the bladder must be washed out at short and regular but increasing intervals for some hours following operation. To my mind this is one of its most unattractive features as instead of the patient being permitted to rest quietly and sleep in his bed during post-operative hours, he is continually disturbed by the rapid filling and emptying of the bladder every few minutes. Furthermore in the odd case a return to theatre for re-examination and coagulation of bleeding points may be required. The application of a solution of "thrombin topical" to the bleeding surface may lessen or remove this sequel to the operation and early reports on its use for this purpose are encouraging.

Sepsis is another and not uncommon complication following this type of operation but the introduction of the sulphonamides and penicillin has undoubtedly lessened its incidence. Recurrence of the obstruction is an acknowledged possibility which may occur at a later period in an appreciable number of cases and a permanent incontinence though rare in the hands of the expert may be a serious complication to those less skilled. Thus I have concluded that, at least so far as I am concerned, per-urethral prostatectomy in the presence of a large adenomatous gland is a much more serious procedure than the radical suprapubic operation and that the results are less satisfactory. I now confine the use of this operation to the types of obstruction to which I have already referred.

(4) *The Harris operation* (1927, 1929, 1933).—My experience with this operation is shown in Table II.

		TABLE II	
Type of patient	Number	Died	Mortality percentage
Private	188	8	4.2
		(2 cardiac failure, 1 uræmia, 1 recurrence of cerebral thrombosis, 2 mesenteric thrombosis, 1 cerebral hæmorrhage one month later, 1 retroperitoneal infection)	
Hospital	130	4	3
		(1 phthisis two months later*, 2 excision of bladder tumour + prostatectomy, 1 uræmia six weeks after leaving hospital*)	
Total	318	12	3.7

*These two cases are, strictly speaking, not operation deaths. If they are excluded the hospital mortality is reduced to 1.5% and the total mortality to 3.1%.

The few modifications I have made in the original technique are I think of importance and have contributed to the results achieved. They are that the anterior transverse suture is passed widely, deeply, and tangentially to the cavity which the needle should not perforate; it should just miss its front wall. I think this stitch is a great factor in controlling hæmorrhage. The second transverse suture transects the cavity and should also be passed widely and deeply and parallel to the first suture but ample room must be left for the indwelling catheter which must not be gripped tightly and in fact the reconstructed internal urethral meatus must admit easily the tip of the index finger. Another modification is that I close the bladder in three layers making a completely air- and water-tight union. Features of Harris' original description which I should like to stress are:—first that the bladder should be empty before it is opened as not only is this procedure much simpler than opening it when full but it lessens contamination of the wound in cases where the urine is already infected; secondly, that the cavity left after removal of the prostate must be smooth and without tags or excrescences, in other words the enucleation must proceed through the line of cleavage and any tags must be excised; and thirdly, the trigonal stitch must be passed from immediately below and behind the mid-point of the inter-ureter bar and then brought forward under the floor of the prostatic cavity which it may enter at any point beyond, that is distal to, the edge of the trigonal flap. The object to be achieved is the fixing down of this flap and the idea that the suture must pick up the posterior edge of the torn urethra, whilst advantageous, is unnecessary. In connexion with the passing of this trigonal stitch two criticisms have been made. First, concerning perforation of the rectum, a catastrophe which I have never met nor have I heard of it occurring in other hands. I have heard fear of it expressed by many but I do not believe that its occurrence is possible if a correctly curved boomerang needle is used. Secondly, cases are on record where a ureter has been occluded by the trigonal stitch. I would point out that no operation is foolproof and that both ureter mouths must be visualized and the stitch passed at a point immediately behind the inter-ureter bar equidistant from the ureters. With this obvious precaution it is practically impossible to include or compress either ureter. Drainage should be by indwelling urethral catheter only but it is imperative to successful drainage that the catheter should be of 22 F gauge with an internal calibre of not less than 15 F. Its tip should be cut off after being passed and before closure of the bladder and it must be adjusted

(3) *Per-urethral resection*.—This method, in its present form, originated in America about 1930 and soon was acclaimed as the ideal treatment for all forms of prostatic hyperplasia. Not only were members of the medical profession swept off their feet by a wave of enthusiasm but the general public, having heard of the new method which obviated a "cutting operation", demanded it. Few now make use of it for every prostatic hypertrophy; most reserve it for the treatment of fibrous glands, the small subcervical adenomata and the case of obstructing carcinoma with impending or actual retention. In America the Mayo Clinic use it in preference to any other form of treatment and Emmett (1944) reports that for the ten-year period preceding 1942, 9,000 resections were performed there with a mortality rate of 1.1% and an average hospital stay of 8.6 days, only 3% requiring further resection at a later period for recurrence of obstruction. In England, Wardill (1947) also uses this method exclusively. He states that his cases are entirely unselected and that he has performed 537 resections during the twenty months prior to August 1947. 26 patients died (4.84%) and 58 required more than one resection (10.8%). On the other hand Millin (1946) after performing 219 resections discarded it, on account of late complications, except in the type of case I have specified. Chapman (1947) states that till recently he employed the method exclusively except for certain bad risk cases which were treated by permanent suprapubic drainage. He reports 379 cases with 24 deaths (6.3%). His present practice is to treat the large adenomatous prostate by suprapubic prostatectomy and 20% of his patients are now so treated.

There are two different methods of performing this operation: (1) by the McCarthy instrument using a cutting loop activated by diathermy electric current to excise the tissue, and (2) by the cold punch instrument, known as the Thompson resectoscope or punch, by which tissue is removed by a circular knife. The McCarthy instrument was first in the field and I gave it an extensive trial. Although of large size the shaft of the instrument required little movement in the urethra during the operation and thus I found the incidence of post-operative stricture was less than when using the punch instrument; its disadvantages were that the lens system, becoming clouded by blood, reduced visibility and made it difficult not only to recognize anatomical landmarks but to resect sufficient tissue and furthermore the operation tended to be prolonged as after each cut the telescope and cutting loop had to be withdrawn with the attached piece of tissue. I discarded the method when I acquired a Thompson punch which I found much simpler to use in that it permitted good visualization despite appreciable hæmorrhage and thus one was able to remove a large amount of tissue in a comparatively short time.

I have performed per-urethral resection on 26% of my cases and that includes a period of one year during which, to gain experience, I used the method almost exclusively: the results are shown in Table I.

TABLE I				
Type of patient	Number	Died	Mortality percentage	
Private..	69	7	10.14	
Hospital	86	8	9.3	
Total	155	15	9.6	

My reaction to the operation, using the cold punch, is that I dislike the large size of the instrument which is stated to be size 30 F but which actually is often size 32 F and thus too large for the normal urethra. A smaller instrument is made but it is much less effective and seldom used. Many of my cases developed severe urethral stricture as a result of the passage of the large instrument. How could it be otherwise when one considers the tightly fitting instrument in the urethra with its constant piston-like movement against the delicate urethral mucosa? It is true that stricture formation can be partially obviated by inserting the instrument through a urethrotomy opening in the bulb but most of us would hesitate to perform this additional, even temporary, mutilation. A further difficulty I found with the instrument was in determining when a sufficiency of tissue had been resected. Time and again I considered that I had removed all obstructing tissue only to find a few days later that the patient still had difficulty in micturating freely or even that retention was still present. A further resection was then carried out and indeed at times resection was necessary on three separate occasions. I believe that this is not an uncommon occurrence but I am willing to admit to some inexperience. Presuming a man to be an ordinary skilled instrumentalist how many resections should be necessary before he could expect to achieve reasonable perfection? I have heard various estimates of from one hundred to three hundred but that seems an immensity of suffering to inflict in the pursuit of even a moderate degree of skill by this method! But there are other defects and the most important of these are hæmorrhage and sepsis. The operation cannot be performed without very considerable blood loss which starts with the first cut and is continued for several hours following it. The blood loss can be made good by transfusion although that is only necessary in a few cases but to prevent

scar would fill many a plastic surgeon with envy. The only advantage of the long vertical mid-line incision is that a finger in the rectum is unnecessary (a matter of no importance) and visualization for spectators is somewhat easier.

Recently a good deal has been heard about patients suffering from bladder spasm following operation. After the Harris operation bladder spasm is almost abolished and certainly it is unusual for patients to complain of anything more than slight discomfort. The late results are perfect as I have determined by a yearly follow-up of 180 consecutive private cases over a thirteen-year period.

(5) *The Wilson Hey operation.*—In 1945 Wilson H. Hey advocated a revolutionary procedure. In cases of acute and chronic retention of urine he condemned slow decompression and urethral instrumentation as primary factors in causing infection with resulting post-operative uræmia. He advised immediate prostatectomy as being the best drainage operation and described his method by which, after enucleation of the prostate, the prostatic cavity was opened widely into the bladder by removal of the trigone up to the ureter mouths and inter-ureter bar, almost complete hæmostasis being effected by diathermy coagulation. He stressed the absolute necessity of passing the urethral catheter from the bladder outwards and of closure of the bladder wound if sepsis was to be avoided. The catheter is removed as soon as possible, usually about the third day. His operative technique is marked by the most strict aseptic ritual and he believes that by his method prostatectomy can be performed aseptically with resulting accelerated healing and that the urine, if sterile pre-operatively, remains sterile.

Hey classified patients into four groups relative to their condition at the time of operation. Group I were what he called perfect cases of any age with no marked systemic disease and residual urine up to 6 oz.—operation mortality 2.1%; Group II had mild systemic disease with residual urine up to 15 oz. and a blood urea of under 80—mortality rate 6.76%; Group III had marked systemic disease with residual urine of 1 to 5 pints and blood urea varying between 80 and 200—mortality rate 16.1%; Group IV all showed evidence of cardiorenal failure and had blood urea over 200—mortality 66.6%. Only 6 cases out of 335 were refused operation because death was too imminent. Over the whole series the operation mortality was 6% but in Groups I and II combined it was 3.4%.

After visiting Hey in Manchester I tried his methods but my experience of them is small. In the more serious cases (Hey's Groups III and IV) in which prudence indicated preliminary rest, restorative measures and slow decompression, 2 out of 4 patients died and I wondered if slow decompression and a two-stage operation might not have given a different result. For the ordinary prostate case (Hey's Groups I and II) the Harris operation to which I was accustomed gave better and more pleasing results in my hands so I returned to it. In spite of that I admire Hey's pioneer work. His conclusions regarding the dangers of sepsis from any form of bladder drainage must I think be conceded but in that connexion I cannot see how the retrograde passage of the urethral drainage catheter, on which he places stress, can have great bearing as *pre-existing* organisms in the urethra are going to ascend to the bladder sooner or later while a catheter remains in situ and thus it matters little whether the catheter is passed in the normal manner or as Hey recommends.

(6) *Retropubic prostatectomy.*—Millin (1945) was responsible for another revolution but this time mainly from the operative angle. He has described an extravesical method of prostatectomy which he has named retropubic prostatectomy and although he may not have been the first person to have thought of removing the prostate by the retropubic route he certainly was the first to devise a workable and relatively simple technique. The method he advocates has all the benefits of exposure and accessibility to the gland given by the perineal approach but is without the dangers of septic contamination and post-operative urinary incontinence inherent in that method. The operation has now been practised for two years and Millin has recently reported a series of 1,700 cases operated on by 16 surgeons, all of whom had carried out more than 50 operations, with an overall mortality rate of 5.3%. His own operative mortality in 439 cases is 4.75% (Millin, 1947a). It is as yet too early to dogmatize about final results but if Millin's present technique is carried out there would appear to be little chance of late complications. To one accustomed to prostatic surgery Millin's operation is not unduly difficult. My troubles concerned post-operative hæmorrhage and fistula. After completion of the operation I was surprised to note that the dressings required changing once or twice during the first six hours owing to their becoming saturated with blood. This occurred after every operation despite the most meticulous hæmostasis and despite the fact that no fall in blood-pressure had occurred during the operation. On only one occasion was it serious and that patient died of a sudden hæmorrhage into the prevesical space five hours after the operation in spite of the wound immediately being reopened and gauze packed and a rapid blood transfusion given. Generally I considered that there was a much greater blood loss from the prevesical drainage tube in the early post-

so that all its "eyes" will lie within the bladder and none within the prostate cavity as otherwise clot from the cavity may enter and occlude it; the position of the "eyes" is such as to secure adequate and immediate drainage of blood. I fix this catheter by a suture stitched to the wall of the catheter near its tip. One end of the suture is then attached to a large curved needle which should perforate the bladder wall from within at a point about 2 in. lateral to the line of the bladder incision where it is pushed through to the skin surface; the other end of the suture is similarly brought out on the skin surface on the opposite side. After closure of the abdominal wound a thin rubber tube, of a length sufficient to bridge the gap between the cutaneous exit points of the ends of the suture, is threaded on one end and the two ends are then loosely tied.

After closure of the bladder sulphathiazole powder is freely applied to the deep and superficial parts of the wound and also to the skin edges. A small tube is left to drain the prevesical space and the abdominal wall is closed around this by two silkworm sutures supplemented by a few Kifa clips. The wound is sealed by elastoplast over a few layers of gauze and this dressing is not disturbed for five days but a small hole in the centre of the elastoplast permits drainage from the prevesical tube and its withdrawal in forty-eight hours. Absorbent wool retained by a binder and easily changed covers the elastoplast. Finally the bladder is irrigated through the catheter and when the return is pink-coloured the bladder is emptied and 4 oz. of a 10% sodium citrate solution are instilled and the tube spigotted till the patient is returned to bed, following which 10 oz. of normal saline solution is administered rectally and the catheter connected to a bedside drainage flask by rubber tube. Later 1/6 grain of morphia is administered hypodermically. That is practically all the immediate after-treatment necessary but it is important that a nurse should watch that the urine continues to drip into the sterile bedside bottle. Irrigation of the bladder through the catheter is not permitted unless the urine fails to drip. If this should occur the nurse may force 2 oz. of saline solution, by means of a syringe, through the catheter and at once forcibly aspirate the amount inserted. If she fails to get a return the sister or house surgeon must be called but this is seldom necessary. Clot retention is uncommon and in most of the patients in which it has occurred it has been possible to clear the catheter by vigorous suction using a 2 oz. glass syringe. Where this fails, as it has on a few occasions, the catheter must be withdrawn, a Bigelow cannula inserted and the clot removed by an evacuator. I have found this method efficacious and in my experience it has never been necessary to reopen the bladder for clot retention. On the following morning patients treated by this operation feel and look well and are generally sitting up in bed reading their newspapers. Complications are practically unknown. The catheter is withdrawn whenever the urine is clear, usually in from six to eight days, and never later than the tenth day and following that natural micturition is re-established, the wound at that time having healed by first intention.

Patients after this operation may sit up out of bed in twenty-four hours but I never force a patient to get up against his will and usually he does not do so until the day on which the catheter is removed. The urine always shows some infection, generally a slight bacilluria following the operation but this can be cleared up in about a fortnight by treatment with sulphonamide.

The picture I have drawn is one which can be expected in any case where the general condition of the patient is fairly satisfactory and the urine sterile before operation. Where the urine is not sterile or where prolonged catheter or suprapubic drainage is required pre-operatively the urine takes longer to become sterile and a small quantity may leak through the suprapubic wound for a few days after withdrawal of the catheter.

I have found this operation with immediate closure of the bladder most satisfactory. I cannot understand why most surgeons still leave a suprapubic tube in the bladder as I believe that not only is that unnecessary but harmful. Fear of clot retention in the presence of a slight ooze from the prostate cavity is responsible for the practice but I would point out that a catheter such as I have described can clear the bladder of any trickle of blood and complete hæmostasis is unnecessary. During the past two years I have never failed to close the bladder at operation and I would go so far as to state that to-day any prostatectomy technique which entails leaving the bladder open even for a short period is undesirable.

There is one further alteration in Harris' original technique which has a considerable bearing on the comfort and rapid uneventful convalescence of the patient and which I regard as of importance and that is that the suprapubic wound should be small, transverse in direction, and situated one fingerbreadth above the pubis. After incising the skin and superficial fascia transversely, the linea alba is divided vertically from the pubis upwards for 2 in. The space thus gained when the recti are separated is amply sufficient for the operation. The opening into the bladder is made high and vertically and should not be larger than will admit the index and middle fingers. With a wound of this type the patient has no post-operative discomfort from his wound and the healing of the skin and subsequent

equally and that there is no gross hydronephrosis or hydro-ureter. (6) Renal function tests should not show a marked deficiency; a blood urea of 50 mg. % is regarded as satisfactory. (7) Urinary output should be about 80 oz. daily. (8) The cardiovascular apparatus should be found to be satisfactory on examination by a physician well cognizant of the amount of strain imposed by each of the possible prostatic operations.

Class II is made up of patients who do not qualify for Class I.—These patients are treated by urethral catheter drainage and are either quickly or gradually decompressed as may seem advisable. The majority of those who survive become fit for a closed method of prostatectomy within two weeks but if, at about that time, they have not done so then a suprapubic tube is inserted into the bladder and the patient is discharged from hospital. Such a patient is put under the care of his own doctor but attends our out-patient clinic at monthly intervals for re-examination. Whenever he shows improvement sufficient to allow prostatectomy he is readmitted and the operation carried out.

The principal hazard in the relief of prostatic obstruction occurs immediately after the patient commences treatment or even before treatment is instituted. Table IV shows this clearly and it proves that many patients are presented for treatment either at a late stage in the disease or even when death is already imminent. It provides a serious warning of the dangers of delay.

TABLE IV.—MORTALITY FROM PROSTATIC OBSTRUCTION

	Number	Died
Total number of consecutive cases admitted to hospital with prostatic obstruction.. .. .	260	31
A.—Treated by prostatectomy (all methods)	187	16
B.—Treated by drainage alone or receiving no treatment ..	73	15

Few patients who survive drainage fail ultimately to satisfy the criteria we consider necessary for safe prostatectomy and indeed our records show that, excluding prostatic carcinoma, less than 5% have been condemned to a permanent suprapubic tube. Commonly we have patients referred to us who have worn a suprapubic tube for months or years and have been refused prostatectomy elsewhere on account of their poor general or urinary condition. I believe there are few more distressing conditions for a patient than to be condemned to permanent bladder drainage and thus it often happens that such a patient will plead for relief even when fully aware of the considerable risk to life which, in his case, may be attached to radical operation. With careful pre-operative treatment it is surprising how many of these "elderly wrecks" can be given a new lease of life by a rapidly performed Freyer type of operation. A closure operation or any operation requiring more than ten minutes anaesthesia is usually unsuitable.

589	41	6.96

CONCLUSIONS

In the first place I should like to make it clear that in my opinion there is at the present time no single operative procedure suitable for all types of prostatic obstruction and I maintain that the type of operation should be adapted to the conditions presented by the patient. Many factors govern the choice, such as the condition of the prostate itself, the state of the urinary tract, the configuration and general health of the patient, his age and infirmities and especially the condition of his cardiovascular system. Thus it comes about that I view with misgiving the assessment of the difficult case by the surgeon alone; the prostate case can present such complex medical problems that if the best is to be done team work is essential and the team must include a physician experienced in the examination and treatment of this type of case. Another important factor in determining the type of operation is the "set up" of the hospital or clinic in which it is to be performed. It is wrong to undertake the treatment of prostatic obstruction except in a modern clinic where every aid, scientific, instrumental and human, is available. Except in dire emergency, a hardly conceivable condition in prostatic surgery, or in very exceptional circumstances, the urologist should refuse, for the reasons I have mentioned, to operate away from his own hospital clinic or nursing home. The general body of practitioners and the general public have such an experience of badly planned and performed prostate operations, with mortality in the region of 20% and a shocking morbidity, that the evil day of seeking or taking advice is deferred till conditions have so deteriorated as to make a perfect result unlikely. Only now with a better technique and better resources are we beginning to break through the

operative hours than occurred following the Harris operation. Other troubles from hæmorrhage occurred in cases where the bladder neck had to be resected widely. This resection left an opening into the bladder much larger than the catheter so that any bleeding from the prostate bed tended to ooze back into the bladder where it clotted and this often led to the catheter becoming blocked, and indeed on two occasions evacuation of the clots by the Bigelow evacuator was necessary. I have no doubt that this was the result of inefficient hæmostasis in the prostate bed and bladder neck and it shows the necessity for the identification and ligation or coagulation of all bleeding points. I cite this as a warning to those trying the operation. Another trouble was leakage from the suprapubic wound after withdrawal of the catheter. With a pre-operative sterile urine the suprapubic wound healed by first intention in all cases and after withdrawal of the catheter there was no ooze of urine from the wound but it was otherwise in some cases with a pre-operative bacilluria. These patients micturated normally after withdrawal of the catheter but most of them showed some leakage from the wound which persisted for from two or three days to as long as twenty days. In the same type of infected case treated by the Harris operation the fistula closed in a much shorter time. My nursing staff and my assistants concluded unanimously that the results we achieved by the Harris technique were on the whole better than by the Millin method. That finding may be peculiar to myself and detracts in no way from my admiration for this excellent method of prostatectomy and indeed I may, through later experience, use this technique more frequently.

The following table of my results with this technique is not a true reflex of the operation and only one death, which I have already described, can be attributed to the operation itself. At the time I was doing a series of retropubic operations I became temporarily imbued with Hey's teachings and I thought that if Hey's operation was suitable for use as a drainage operation in the very poor risk case with chronic overflow incontinence and high blood urea there appeared little reason why the retropubic operation should not prove equally satisfactory. Two of the deaths were accounted for by that view. The other deaths were due to coronary thrombosis in one and cerebral thrombosis in the other.

TABLE III

Type of patient	Number	Died	Mortality percentage
Private..	6	2	33·3
Hospital	24	3	12·5
Total	30	5	16·6

(7) *Perineal prostatectomy*.—This method of prostatectomy has never achieved popularity in this country although in America it had and still has a considerable vogue. Its main disadvantage is the possibility of urinary incontinence due to interference with the external sphincter. In the treatment of early carcinoma the route is a good one but the site of the wound is in an area exposed to septic contamination and thus the retropubic approach of Millin appears preferable (Millin, 1947*b*). My own experience of the operation is too small to be of any value.

(8) *The two-stage operation*.—By the two-stage operation I mean a preliminary cystostomy and bladder drainage as a first stage followed at a shorter or longer interval by removal of the prostate as a second stage. Any form of bladder drainage means urinary sepsis and thus it follows that, if at all possible, preliminary drainage should be avoided and post-operative drainage limited to the shortest possible time. Having admitted that, one has to consider the condition of the patient and his urinary tract and determine what will be safest and best for the particular case. The two-stage operation is undoubtedly a safer procedure for the inexpert but for the specialist the one-stage operation is in my opinion much to be preferred from all points of view. I find that I have performed a two-stage operation in approximately 6% of all cases.

METHOD OF SELECTION OF OPERATION

In my clinic in the Western Infirmary, Glasgow, we divide cases of prostatic obstruction into two classes:

Class I consists of those cases where preliminary drainage is unnecessary and a single stage operation can be safely performed.—The criteria we consider necessary for this are (1) There should be no palpable bladder distension or if distension is present it should not reach beyond a point midway between pubis and umbilicus. (2) The urine should not be grossly infected. (3) There should have been no recent urethral instrumentation apart from an indwelling urethral catheter. (4) Serious calculous disease should be excluded by X-ray examination. (5) Intravenous urograms should show that both kidneys are functioning

to various degrees of inactivation in the presence of some of the common organisms producing urinary sepsis, but in their absence it holds an important place and even in their presence may prevent pyelonephritis (Yates Bell, 1947) by acting as a remote barrier to the spread of infection. Either or both of these drugs should be used prophylactically and therapeutically. Their use has almost revolutionized prostatic surgery by removing fear of sepsis following the closure operations and already many report a very striking decrease in operative mortality (Yates Bell, 1947; Morson, 1947 *a, b*).

In cases where infection of the urine following operation persists after fourteen days of sulphonamide treatment, I give weekly courses of a mandelic acid preparation and sulphonamide alternately. This generally cures but in patients with a long history of prostatic obstruction and in whom pre-operative sepsis was marked the condition may be extremely intractable.

(3) *Suprapubic fistula*.—Reference to fistula formation following the Millin operation has already been made. Fistula following the Harris operation is uncommon. 77% heal by first intention, and in the remaining 23% healing is complete in about twenty days. In my cases no fistula persisted or required any form of secondary operation. In patients treated by the Freyer technique, where a suprapubic tube is used for drainage, fistula formation persisted for over fourteen days in about 75% of cases and in these the average time of closure was thirty days. No permanent fistula resulted from any type of operation and obviously such a condition persisting over months should not occur.

(4) *Post-operative urethral stricture*.—Reference has already been made to the incidence of severe stricture following per-urethral resection by the Thompson resectoscope; it is one of the great disadvantages of that operation. In no case did it occur after the Millin operation and in only a very few cases was there a minor degree of stricture following the Harris operation. Urethritis due to an indwelling catheter is also a common cause of this condition.

(5) *Incontinence*.—Incontinence following the Millin, Hey or Freyer operations has not occurred. Following the Harris operation a temporary total incontinence occurred in 1.4%. At first this puzzled me but cystoscopy showed it to be due to sloughing of tissue caused by over-tightening of the transverse sutures in the prostate cavity. This slough, about 1 cm. in diameter becoming partially impacted in the bladder outlet, interfered with sphincter action. The condition was completely cured with the passage of the slough which occurred naturally in all cases and caused no secondary hæmorrhage or after-effects.

(6) *Epididymitis*.—Every prostate operation should be preceded by bilateral vasectomy. This procedure takes four minutes and is done through bilateral small 1 cm. incisions in the scrotal skin. In no instance have these wounds failed to heal by first intention. In spite of this, epididymitis of minor degree has been known to occur but is uncommon. An inflammatory thickening of the cord proximal to the site of vas resection has occurred in 10% of prostatectomy cases in which there was marked urinary infection, but has gradually disappeared after a few days.

(7) *Urethritis*.—This rarely occurs post-operatively where there has been no pre-operative urethral drainage. If it does occur the catheter is at once withdrawn and intensive sulphonamide treatment instituted. In a patient treated by a closure operation where the catheter has had to be removed in the early post-operative period all the urine may be passed *per urethram* but, on the other hand, part may ooze through the suprapubic wound. Extravasation or serious complications have not occurred but a suprapubic fistula may form and may take a week or two to heal. Should urethritis develop during pre-operative drainage the catheter may have to be withdrawn and the operation performed by the two-stage method, but if intensive penicillin-sulphonamide treatment is instituted at once the infection may be aborted without necessitating removal of the catheter. Taken all over, urethritis has been uncommon in our hands largely on account of two factors, first, the institution of routine chemotherapy during the period of catheterization, and secondly because catheterization is performed with great care and gentleness. The catheter itself is anchored in position by the pipe-cleaner method, or a small self-retaining catheter of Foley type is used. Furthermore, while the catheter remains in the urethra a gauze dressing soaked in acriflavine 1:1,000 surrounds the glans penis and the first centimetre of the protruding catheter; this dressing is changed daily. Furthermore I believe it is important that the catheter should be a loose fit in the urethra to permit drainage of mucus, also that it should be held steady and not allowed to move: this is achieved by surrounding the penis with gamgee which along with the catheter is strapped to the thigh. While the catheter remains in the urethra the patient is not allowed to walk about although he may sit on a chair.

(8) *Pulmonary embolism*.—This occurred occasionally following all forms of prostatectomy till about two years ago. Only one case was serious, the patient dying within a few minutes on the third day following an open diathermy resection of a fibrous prostate. The others

crust of professional and lay resistance to early treatment and thus I maintain that there must be no setback in the position.

COMPLICATIONS AND SEQUELS OF PROSTATECTOMY

In recent years a good deal has been written about the complications and sequels of prostatectomy.

(1) *Hæmorrhage*.—(a) *At operation*: It seems hardly possible to perform prostatectomy without blood loss to the extent of from a half to one pint. Some patients bleed more than others but in all cases efforts must be made to minimize this loss. I have found that rapid but gentle enucleation of the gland, adhering rigidly to the line of cleavage with minimal tearing of tissue, limits the bleeding. Immediately the gland mass is freed and displaced from the prostatic cavity but before its removal from the bladder, I rapidly pack the cavity with gauze freshly wrung out of hot 1 : 1,000 acriflavine solution. This minimizes further bleeding while retractors are placed and the succeeding stages prepared. When all is ready the gauze is removed, any tags excised and the hæmostatic suture placed and tied. This takes five to ten minutes to accomplish and any further blood loss is trifling. I consider that this limitation of bleeding is one of the features of the Harris operation as I practise it and accounts for the lack of shock, rapid recovery and sense of well-being experienced by the patient within twelve hours of operation. Blood transfusion I rarely find necessary or desirable. In operations where bleeding is not fully controlled by suture, ligature or coagulation, a Foley type of catheter is useful. Recently attention has been focused on the use of "thrombin topical", and oxidized absorbable gauze, as hæmostatic agents in the prostate cavity. The former is injected into the cavity and the latter used as packing (de Vries and Buchanan, 1947) or as a covering for a dilatable bag (MacDonald and Powell, 1947). I have no experience of these hæmostatic agents in prostatic surgery and though they are probably unnecessary for the Harris, Hey or Millin operations, in transurethral resection or the Freyer operation they may prove of considerable value. Bandler, Roen and Stept (1947) have reported on 50 cases of per-urethral resection who received an injection of 10 c.c. of a solution containing 10,000 units of "thrombin topical" through an undistended Foley catheter into the prostate cavity immediately following the operation. Five minutes later the catheter balloon was distended and inserted into the cavity. The catheter was then clamped for one hour, after which it drained continuously. Irrigation was contra-indicated and unnecessary, post-operative bleeding being practically abolished. Chapman (1947) has used this technique in 36 cases, reports that irrigation is unnecessary and that the urine remains only blood tinged for a few days. He had no case of clot retention and he considers that the gain in comfort of the patient and convenience to the nursing staff was enormous. This means of eliminating bleeding may abolish most of the blood loss following the per-urethral and Freyer methods of prostatectomy, and it seems worthy of trial.

(b) *Reactionary*: The special No. 22 F rubber urethral catheter adequately drains off the slight ooze of blood which follows a Harris prostatectomy. The urine remains deeply blood-stained for twenty-four hours after which the hæmorrhage diminishes but as a rule it continues for four or five days—varying in degree from patient to patient. Clot retention following closure operations is rare and is best treated by removing the catheter, evacuating the clots by Bigelow evacuator and reinserting the catheter without necessarily removing the patient from his bed.

(c) *Secondary*: There appears to be some discrepancy in medical literature regarding the time of onset of secondary hæmorrhage. I would define it as hæmorrhage occurring from seven to fourteen days after operation and generally due to sepsis. I have found it to occur rarely, in fact my records show only 2 cases following the Harris operation. Both commenced a few hours after withdrawal of the catheter on the tenth day and in neither was sepsis a marked feature. Treatment by evacuation of the clot by Bigelow evacuator and reinsertion of a catheter for forty-eight hours was successful and convalescence was not delayed. When I say that the condition is a rare one I refer to massive hæmorrhage and not to a slight tinging of the urine with blood during the period within which secondary hæmorrhage might occur. This trivial secondary hæmorrhage is common and can be entirely disregarded, disappearing spontaneously within a few hours.

(2) *Sepsis*.—I do not believe that it is possible for any patient undergoing prostatectomy to escape some degree of septic infection. Indeed Riches and Muir (1933) reviewing all prostatectomy cases in the Middlesex Hospital between 1924 and 1931 found infection to be one of the commonest post-operative complications and the incidence of ascending infection to be appreciable. Recently Skyrme Rees (1947) has shown that over 50% of deaths following prostatectomy are due to severe sepsis in the urinary tract. The sulphonamides have proved of the greatest value in prophylaxis and treatment. Penicillin is said to be less useful owing

I think it is our duty as teachers to impress upon students the importance of making a digital examination of the rectum in as many patients as possible so that they may learn to distinguish the normal from the abnormal prostate, an art only acquired by experience. To the expert, diagnosis of prostatic carcinoma by rectal palpation is usually not difficult but I have been impressed by the frequency with which an obvious carcinoma has been missed by experienced surgeons; the reverse is equally true, and many cases labelled carcinoma have been proved to be non-malignant. Inflammatory conditions or calculi are often responsible for this error. Disturbance of the acid serum phosphatase is too uncertain to make it of value as a diagnostic aid. In many of my cases this has been found to be within normal limits when the patient had an advanced carcinoma of the prostate with multiple bone metastases. Statistics regarding the incidence and treatment of cancer are of no value unless the diagnosis is confirmed histologically. When a cancerous condition of the prostate is diagnosed by rectal palpation I am of opinion that even total prostatectomy will generally fail to avert a fatal issue and this applies equally to the more heroic partial excision of bladder, seminal vesicles, and prostate. In considering treatment for these patients one must bear in mind Morson's finding as a result of his experience in a large Local Authority hospital where patients may remain for years. He states that when treatment consists of nothing more than efficient nursing care and suprapubic drainage the expectation of life after diagnosis has been made is about three to five years (Morson, 1936). To provide efficient nursing care is difficult but if it can be secured one should consider whether the result likely to be achieved by a long and dangerous operation is worth while or the risk justifiable. The administration of stilboestrol often results in a shrinkage of the growth followed by natural micturition and thus operative procedures to relieve retention such as cystostomy or per-urethral resection may be delayed or avoided. It is my impression that the cases of carcinoma of the prostate likely to be cured are those in which the disease is buried within an adenomatous gland and in which the presence of the growth has been unsuspected and only proved at routine histological examination of the excised gland. It thus appears to me to be most unwise to perform the severe operation of total prostatectomy as a routine procedure on the chance that cancer might occur in that part of the prostate left after simple enucleation. Lowsley (1940) believes that total prostatectomy should be done more often than at present. He uses the perineal route and advises it in early cancer, chronic pyæmia, intractable chronic fibrosis, calculosis and certain cases of tuberculosis and adenoma of the prostate. In this country Anderson (1947) states that to those cognizant of perineal prostatectomy the operation is not difficult and the post-operative course is remarkably smooth but that there is a slight risk of incontinence. He has only done a very few cases and thus as yet is not in a position to form any conclusion as to its usefulness.

ANÆSTHESIA

The part played by recent advances in anæsthetic methods in relation to prostatic surgery has resulted in a considerable lowering of operation mortality.

At present I prefer induction by intravenous pentothal sodium, the anæsthesia being maintained with cyclopropane and minimal quantities of ether. Lately relaxation has been increased by the coincident use of d-tubocurarine chloride with excellent results, ether being omitted. Maintenance of normal blood-pressure during operation is of importance in any major procedure, but especially is this so in operations designed to permit immediate bladder closure, as more than a trivial fall in blood-pressure may obscure bleeding points resulting in subsequent hæmorrhage and clot retention.

Some years ago most prostatectomies were performed under spinal anæsthesia with coincident risk of a sudden and often uncontrollable fall in blood-pressure. With this method bleeding points, as already indicated, are obscured just when they should be visible and could be controlled and, in addition, the patient often exhibits signs of shock. Wilson Hey prefers spinal anæsthesia but emphasizes that it should never reach as far as the umbilicus, upward extension being controlled when light anæsthesia reaches a point midway between the pubis and the umbilicus. He maintains that if the anæsthesia is so restricted the fall in blood-pressure is minimal, 30 mm.Hg being the maximum permissible. I have found that the maintenance of such a level of anæsthesia presents considerable difficulty and much prefer general anæsthesia as described.

The anæsthetist must have opportunity to study each patient before operation with a view to assessing his general condition, fitness for the proposed procedure, and such factors as may influence the choice of anæsthetic. Generally speaking anæsthesia requires to be maintained for approximately one hour during which time the pulse should remain regular and the blood-pressure show little or no variation. There should be few after-effects; vomiting or nausea occurs in only a small minority of cases and chest complications are almost unknown.

were of trivial type, the embolus signifying its presence by a sharp pain in the chest and a rise in temperature, followed for a few days by a blood-tinged sputum; the condition resolved rapidly. Two years ago our consulting physician advised the administration of strychnine by mouth (5 minims of liq. strych. hydrochlor. dil. t.i.d.) for two days before operation, and for the days immediately following the operation that drug administered hypodermically, 1/30 gr. being given first followed by 1/60 gr. four-hourly during the succeeding twelve hours, after which administration by mouth may be resumed. Since then we have had no case of embolism, probably due to the effect of the strychnine on the circulatory and respiratory systems. In addition a knee pillow is forbidden and, on complete recovery from the anæsthetic, the patient is taught deep breathing exercises which are carried out at stated periods daily. He is also instructed to move about in bed and limb exercises are prescribed.

Recently articles have appeared in America describing prophylactic surgical treatment for a possible post-operative thrombosis. According to Allen (1947) any patient over 65 years of age who is to be confined to bed for some time should have bilateral superficial femoral vein ligation performed especially when a varicose condition of the veins of the leg exists. The even more drastic procedure of ligation of the inferior vena cava is recommended by Thebaut and Ward (1947) in the case of patients who have suffered one or more small pulmonary emboli. These procedures seem fantastic judged by experience in this country but conditions elsewhere may be different: surely as Bauer (1947) has stated, heparin or dicoumarol should prove equally effective. Prolonged operations probably encourage thrombosis and embolism, thus limitation of operation time is very important.

(9) *Osteitis pubis*.—4 cases have been reported by Yates Bell (1947) and 2 by Riches (1946). The incision which I employ for prostatectomy involves splitting of the linea alba right down to the pubes and possibly on occasion this might cause a wound of the periosteum which is thus exposed to infection from septic urine contamination but even so osteitis pubis has never occurred in my practice and thus Riches' suggestion that the condition is probably caused by lymphatic spread from a low-grade pelvic cellulitis may be correct. The condition is obviously one of some rarity and is likely to disappear with the more general use of chemotherapy.

(10) *Œdema of the penis*.—This occurs in a few cases following both the Millin and Harris operations. It may be due to interference with the venous return by sutures or ligatures which occluded tributaries of the deep dorsal vein, but as a rule rapidly disappears and is of little significance.

(11) *Meteorism*.—The occurrence of this condition following prostatectomy seems to be not uncommon in the experience of some urologists. I have only seen it in minor degree and it has never caused much trouble. Its occurrence may be the result of inefficient pre-operative preparation and the type of anæsthesia employed. The transverse incision and gentle treatment of the small part of peritoneum exposed at operation are probably factors in lessening its incidence and severity.

TREATMENT

(a) *Pre-operative*.—As the average age of the patient coming to prostatectomy is about 67 years his tissues generally show signs of deterioration and thus he cannot be treated as one in the prime of life. Irrespective of age or fitness I consider that he should spend two or three days resting quietly in bed, becoming acquainted with nurses and sick-room hygiene. A good night's rest in the new and strange surroundings is assured by the administration of a mild sedative and the strychnine, as described, administered. Intravenous urography, blood urea estimation, &c., are performed during this time. Cystoscopy or other urethral instrumentation should have been carried out previously or, if not, should be left till the patient is on the operating table where it can be performed immediately prior to the commencement of the operation. The surgeon personally must examine the patient and decide which type of operation is indicated. On no account must this be left to a house surgeon.

(b) *Post-operative*.—Post-operative treatment has already been described and I would only add that on leaving hospital patients are required to report at six-weekly intervals as I do not regard cure to be complete until the urine is sterile and micturition normal; this may be a policy of perfection not always achieved but it is nevertheless desirable.

CARCINOMA

So far I have dealt only with simple conditions of the prostate gland but unfortunately carcinoma of the gland is also a common cause of obstruction. Its incidence compared with simple enlargement is stated to be 1:5 but in my own experience it has been 1:6. Time does not permit a detailed consideration of this disease but I would like to make a few general observations.

I think it is our duty as teachers to impress upon students the importance of making a digital examination of the rectum in as many patients as possible so that they may learn to distinguish the normal from the abnormal prostate, an art only acquired by experience. To the expert, diagnosis of prostatic carcinoma by rectal palpation is usually not difficult but I have been impressed by the frequency with which an obvious carcinoma has been missed by experienced surgeons; the reverse is equally true, and many cases labelled carcinoma have been proved to be non-malignant. Inflammatory conditions or calculi are often responsible for this error. Disturbance of the acid serum phosphatase is too uncertain to make it of value as a diagnostic aid. In many of my cases this has been found to be within normal limits when the patient had an advanced carcinoma of the prostate with multiple bone metastases. Statistics regarding the incidence and treatment of cancer are of no value unless the diagnosis is confirmed histologically. When a cancerous condition of the prostate is diagnosed by rectal palpation I am of opinion that even total prostatectomy will generally fail to avert a fatal issue and this applies equally to the more heroic partial excision of bladder, seminal vesicles, and prostate. In considering treatment for these patients one must bear in mind Morson's finding as a result of his experience in a large Local Authority hospital where patients may remain for years. He states that when treatment consists of nothing more than efficient nursing care and suprapubic drainage the expectation of life after diagnosis has been made is about three to five years (Morson, 1936). To provide efficient nursing care is difficult but if it can be secured one should consider whether the result likely to be achieved by a long and dangerous operation is worth while or the risk justifiable. The administration of stilboestrol often results in a shrinkage of the growth followed by natural micturition and thus operative procedures to relieve retention such as cystostomy or per-urethral resection may be delayed or avoided. It is my impression that the cases of carcinoma of the prostate likely to be cured are those in which the disease is buried within an adenomatous gland and in which the presence of the growth has been unsuspected and only proved at routine histological examination of the excised gland. It thus appears to me to be most unwise to perform the severe operation of total prostatectomy as a routine procedure on the chance that cancer might occur in that part of the prostate left after simple enucleation. Lowsley (1940) believes that total prostatectomy should be done more often than at present. He uses the perineal route and advises it in early cancer, chronic pyæmia, intractable chronic fibrosis, calculosis and certain cases of tuberculosis and adenoma of the prostate. In this country Anderson (1947) states that to those cognizant of perineal prostatectomy the operation is not difficult and the post-operative course is remarkably smooth but that there is a slight risk of incontinence. He has only done a very few cases and thus as yet is not in a position to form any conclusion as to its usefulness.

ANÆSTHESIA

The part played by recent advances in anæsthetic methods in relation to prostatic surgery has resulted in a considerable lowering of operation mortality.

At present I prefer induction by intravenous pentothal sodium, the anæsthesia being maintained with cyclopropane and minimal quantities of ether. Lately relaxation has been increased by the coincident use of d-tubocurarine chloride with excellent results, ether being omitted. Maintenance of normal blood-pressure during operation is of importance in any major procedure, but especially is this so in operations designed to permit immediate bladder closure, as more than a trivial fall in blood-pressure may obscure bleeding points resulting in subsequent hæmorrhage and clot retention.

Some years ago most prostatectomies were performed under spinal anæsthesia with coincident risk of a sudden and often uncontrollable fall in blood-pressure. With this method bleeding points, as already indicated, are obscured just when they should be visible and could be controlled and, in addition, the patient often exhibits signs of shock. Wilson Hey prefers spinal anæsthesia but emphasizes that it should never reach as far as the umbilicus, upward extension being controlled when light anæsthesia reaches a point midway between the pubis and the umbilicus. He maintains that if the anæsthesia is so restricted the fall in blood-pressure is minimal, 30 mm.Hg being the maximum permissible. I have found that the maintenance of such a level of anæsthesia presents considerable difficulty and much prefer general anæsthesia as described.

The anæsthetist must have opportunity to study each patient before operation with a view to assessing his general condition, fitness for the proposed procedure, and such factors as may influence the choice of anæsthetic. Generally speaking anæsthesia requires to be maintained for approximately one hour during which time the pulse should remain regular and the blood-pressure show little or no variation. There should be few after-effects; vomiting or nausea occurs in only a small minority of cases and chest complications are almost unknown.

I have to acknowledge my indebtedness to Dr. J. A. W. McCluskie, Dr. W. B. Kyles and Dr. H. H. Pinkerton, physician, bacteriologist and anaesthetist respectively, for their co-operation and team work in the treatment of my cases of prostatic obstruction over a period of many years and to Mr. W. A. MacLennan and Mr. W. Laird Milne for their skilled surgical assistance and to Mr. A. I. L. Maitland for painstaking investigation of case records.

The Influence of the Small Animal Breeder on Biological Research. [*Abridged*]

PRESIDENT'S ADDRESS

By R. E. GLOVER, F.R.C.V.S.

THE biological worker who is concerned with physiological or abnormal conditions both in the human and in animal species depends in no small measure on the quality of the animals available to him for experimental purposes. The breeder who provides the stock plays an important role since the conditions under which animals are raised in the breeding establishments may profoundly influence the results of the scientific worker. The various problems which confront the breeder are therefore bristling with interest and have not always received the attention which they merit.

As it is obviously impossible to cover more than a fraction of this field I have confined myself to three main sections dealing first with the care and maintenance of normal stock with special reference to the influence of diet on susceptibility and resistance, secondly with the influence of disease, particularly latent infections, on biological research and finally with steps which may be taken to co-ordinate and improve breeding animals.

General considerations.—The suitability of various types of buildings, cages, bedding, &c., was adequately discussed at two recent meetings on animal management (Farris *et al.*, 1945) (Biol. Methods Group, Soc. Publ. Analysts, 1947). It is scarcely possible to lay down exact requirements since the planning of buildings and equipment is a matter of individual taste: provided animal rooms are well lit, well ventilated and are easily washed down, cages are of adequate size and frequently cleaned and sterilized, and well-balanced rations are offered in a manner which prevents faecal contamination, an infinite variety of methods can be adopted. I would, however, stress the desirability of dividing animal houses into relatively small units. Admittedly there may be a slight increase in the labour required, but this is offset by the advantage of ease of isolation of stock into small units in the event of an outbreak of an epizootic.

The common diseases of small animals have been recently reviewed by Ratcliffe (1945) and by Parish (1947) who gave excellent advice as to the steps to be taken to secure their elimination. Special precautions may be necessary in the well-conducted Institute in which diseases have been avoided or are well under control since it is conceivable that in the absence of constant exposure to infection, highly susceptible races may develop. Ratcliffe (1945) has observed that: "Under natural conditions the species from which laboratory animals are derived are subject to many of the same infections that occur in captivity, yet they survive and multiply. One wonders, at times, whether or not efforts have been misdirected. Possibly colonies of laboratory animals should be fully exposed to infections, until by selection, highly resistant strains are obtained. Certainly, present-day efforts to exclude infection develop highly susceptible races." This ideal may sound attractive to the individual who is solely responsible for a normal breeding unit, but one may venture to doubt whether the experimentalist, who is frequently seeking the most sensitive animal, would be wholeheartedly in favour of uniformly resistant stocks. Such strains might be of value if resistance was highly specific for a particular group of organisms, e.g. *Salmonella*, and was "fixed" and invariable. There is no evidence, however, that "resistant" strains are not always undergoing modifications; moreover "resistance" is usually broad and may cover a variety of infecting agents. In the present state of our

knowledge it is probably wiser to adhere to strict quarantine measures and a constant laboratory check on incipient outbreaks of disease.

Diet.—It is highly desirable that the personnel responsible for breeding stocks should receive some elementary training in the compounding of rations and on the deleterious effects of ill-balanced diets. The present tendency is in the direction of cubed or pelleted foods which have advantages over wet mash and loose mixtures. They can be offered in wire baskets thus avoiding undue wastage, soiling with excrement is reduced to a minimum and provided they are prepared by a reliable firm, should give constant results. As far as this country is concerned particular attention may be drawn to the work of Watson (1937*a*) and Parkes (1946) who have provided useful data on fertility, weaning rates and growth of mice. Bruce and Parkes (1946, 1947; Bruce, 1947) have extended the use of pelleted food to rabbits and guinea-pigs; these diets contain such ingredients as bran, oats, barley meal, lucerne meal, &c. It must be stressed, however, that if it is desired to rear a colony on cubed food alone without the addition of any supplements of fresh food, it is essential to ensure that the ingredients are of the highest quality. There is an obvious danger that if a particular item is in short supply or is expensive, the manufacturers may be tempted to use a substitute material. The breeder should obtain a firm assurance that a compounded food will not be altered without notification and unless he can rely on such a guarantee he may run a risk of serious disturbances in his breeding stock which may well prove disastrous. For example, it has been shown under experimental conditions that the diet devised by Watson is satisfactory when it contains yeastrel. It was found, however, that if the yeastrel was replaced by an amount of dried yeast apparently equivalent to the yeastrel, there was a 50% drop in fertility in breeding mice within a few weeks while the young stock showed obvious signs of thiamine deficiency.

The problem of providing suitable pelleted foods for guinea-pigs and rabbits is more complex owing to the necessity for incorporating some form of green vegetation and in the case of guinea-pigs, vitamin C. Attempts to rear these species on purified diets suitable for rats have not been successful (Loosli, 1945). In the case of guinea-pigs the missing substances are present in fresh vegetation and a diet adequate in respect of protein, carbohydrate, &c., may not maintain growth unless supplemented with fresh green food. Bruce and Parkes (1947) reported, as we had noted in earlier experiments (Platt and Glover), that a good quality dried lucerne meal contains sufficient vitamin C to maintain the animals, but that when added to a compound ration and pelleted, the loss in ascorbic acid was often so high as to render the mixture inadequate to prevent scurvy. The former state that they can find no evidence that pelleted diets are deficient in any factor other than ascorbic acid. There are valid reasons for supposing, however, that the substances mentioned by American workers as "grass juice" factors are not a figment of the imagination. We have found that a synthetic diet composed of starch 64%; casein 24%; dried yeast 8%; salt mixture 4%; and vitamins A, D and E will give as good growth curves in guinea-pigs as "natural" diet provided a green-food supplement is added. The points to note are: (1) guinea-pigs fed on this mixture without lucerne meal die rapidly with symptoms of acute scurvy; (2) the addition of ascorbic acid improves the diet but growth is slow, reaches a peak and then declines, the animal eventually dying. There are signs of muscular dystrophy but no *macroscopic or microscopic evidence of scurvy*; (3) the addition of dried lucerne meal or of an autoclaved aqueous extract of green food gives normal growth curves; (4) amounts of lucerne meal as low as 2% may be adequate; since they contribute at the most 0.5% of protein to the diet, the protective effect is not due to protein deficiency in the basal ration; (5) autoclaved milk can delay the onset of death in guinea-pigs deprived of lucerne meal. The difference in activity of various samples of grass meal can be readily detected by feeding the meal at various levels.

Influence of diet on susceptibility or resistance.—Changes in diet which may affect the response of animals to various stimuli may be related to a restriction of diet in

which a condition of semi-starvation is enforced or to an imbalance of individual constituents. In so far as virus diseases are concerned, there is a general impression that the ill-nourished animal is less susceptible than the well-fed beast. A typical example is the variation in the response of rats, and to a less extent guinea-pigs, to foot-and-mouth virus whereby well-fed animals are much more receptive than are those in poor condition (Edwards, 1937).

Sprunt (1942), who reported that the reactions of rabbits to vaccinia virus were more pronounced in animals fed on a normal diet than in those which were semi-starved but given water, has postulated that the poorly nourished cell may be lacking in some of the materials necessary for the formation of new particles. In general, animals in poor condition show some increased resistance to viruses.

So far little evidence has been adduced that individual constituents of a diet can affect susceptibility to virus diseases. Experiments on low protein, or lack of vitamins A, D, and C, respectively, have failed to yield any concrete evidence that these elements play a significant part in the severity of a virus attack. There is a slight indication that the vitamin-B complex may be implicated. The experiments of Foster *et al.* (1944), Rasmussen *et al.* (1943) and others suggest that a depletion of the vitamin-B complex, particularly thiamine, may delay the action of murine poliomyelitis virus on the C.N.S. On the other hand, Zinsser *et al.* (1931) showed that rats which received a normal diet were resistant to the intraperitoneal inoculation of Rickettsiae but became much more susceptible if the vitamins were removed. It would seem, therefore, that the chance of establishing a virus in a laboratory animal might be significantly affected by the diet.

With regard to bacterial diseases there is some evidence that modifications in diet may influence resistance to infection, but unlike virus diseases, susceptibility seems to be enhanced when the diet is inadequate. This effect may be produced by withholding food; as, for example, the lowered resistance of starved mice to *Ery. rhusiopathiae* (Balfour-Jones, 1935).

There is also a general impression that animals receiving a diet grossly deficient in vitamin A are less resistant to both spontaneous and experimental infection (Drummond, 1919; Green and Mellanby, 1928; and others), but the evidence is not conclusive and has been disputed. In this connexion Webster and Pritchett (1924) who infected mice with *S. typhi murium* noted a death-rate of 15.9% when the diet contained 5% butter fat as compared with 77.8% with a fat-free diet. They were inclined to attribute the difference to the high vitamin-A content of their modified MacCallum diet but Watson (1937*b*) has pointed out that the ration also contained a high proportion of dried milk powder and casein: she was inclined to think that the vitamin A played a minor part in enhancing resistance. Certainly experiments of a similar nature carried out by Topley *et al.* (1931) were inconclusive in respect of the role of vitamin A in experimental infection.

The observations of Watson (1937*b*), Watson *et al.* (1938) are particularly interesting; they indicate that mice receiving a diet containing dried separated milk were more resistant to *S. typhi murium* than those fed on a ration free from milk. When exposed to infection by the "closed epidemic" method the percentage of survivors in the milk-fed groups were 56.3 and 75.5 as compared with 18.5 and 39.5 in the others. It is highly probable as suggested by Watson that the positive effect of adding or the negative effect of withdrawing a dietary constituent does not alter specific resistance to a bacterium or toxin but operates by influencing the well-being of the animals. Certainly no substantial evidence has yet been advanced that milk or any other constituent possesses any "anti-infective" factor in a restricted sense.

The necessity for very careful control of diets may have a special application in the standardization of biological products. Hartley in a series of classical experiments has shown that in groups of guinea-pigs fed on a basal diet plus ample cabbage there is a uniform rise in antibody to the injection of a diphtheria prophylactic, in contrast

to the wide scatter in groups receiving a supplement of mangolds and he attributed the difference to an effect of nutrition. The conflict of opinion on the effects of poor diets which in some instances appear to reduce and in others to enhance resistance to infection is difficult to explain. It is possible that the depletion of certain dietary constituents may act independently on the body cells and on the infecting agent. If the somatic cells are deprived of some essential factor and are thus partially "starved", their powers of resistance may be lowered to an extent which may render them more open to attack. On the other hand the virus or bacterium may suffer to a greater extent and possibly at an earlier stage so that in the poorly nourished animal, it perishes from inanition before it has a chance to become established.

In some instances, the passage of new agents to a host which is normally insusceptible may be effected by dietary changes. Thus, Glynn and Himsworth (1944) have set up a form of liver necrosis in the rat with diets low in casein and high in yeast. MacCallum and Miles (1946) have taken advantage of this liver damage and have shown that rats, which normally are completely unaffected when inoculated with the agent causing human infective hepatitis, develop hæmorrhagic lesions in the liver and glands if, prior to injection, they are placed on this methionine-cystine deficient diet.

Breeding stock may also be affected by the addition of deleterious substances to the diet. In one example which came to our notice, a group of 8-months-old guinea-pigs had failed to develop and many showed ascites; post-mortem examination revealed a generalized cirrhosis of the livers. It was then ascertained that several weeks previously the animals had received hay containing a high proportion of ragwort (*Senecio-Jacobea*). Six young guinea-pigs fed on this hay for ten weeks developed acute hepatic cirrhosis.

Changes in temperature can also exert a profound effect on stock. The optimum temperature in mouse and rat rooms is 65° F. to 70° F. and a drop in fertility and growth rates is liable to occur both at higher and at lower levels. Fluctuations in temperature are also liable to influence the response to various biological products, the susceptibility to transmissible neoplasms, nutritional studies, &c. In our own work (Platt and Glover) it has been found that the food intake in guinea-pigs placed on the synthetic diet supplemented with a dried grass meal already described (p. 86) and kept at 42° F. was much higher and the weight increase more rapid than in groups kept at 68° F. If, however, the grass meal was removed the animals at the lower temperature soon lost weight and died at a time when the controls were still in fair condition.

We have observed that mice, normally maintained at 65° F. and transported by van in substantial boxes with ample bedding (twenty-minutes journey) and then returned to a warm environment may show a fall in weight of 2 to 3 grammes in the next twenty-four hours.

It is evident, therefore, that the biological worker who is unable to raise his own animals and is dependent on stock derived from outside breeders should endeavour to maintain close contact with his source of supply. The results of biological research may be materially influenced if he is unaware of the diets offered by the breeder and of the conditions under which the animals are raised. Such information is rarely available in this country but recent trends in the standardization of manufactured foods and a closer control of breeding stock should lead to the raising of a more standard animal.

There is, however, another factor which must not be ignored. If a number of laboratories or individuals obtain a different end-point in the titration of a virus or the standardization of a biological product, it may be suspected, assuming that diet, external temperature and method of handling are identical, that there is some difference in the racial or genetical make-up of the experimental animals. Conflicting results may be avoided by selecting the same *strain*, e.g. Swiss mice, but there are obvious advantages in using inbred strains of proved homozygosity. There is a vast field for the development and wider use of pure-line strains raised under the supervision of a geneticist.

It would be a mistake, however, to rely entirely on such strains for all types of biological research since in some circumstances pure-line stock may be disadvantageous as, for example, when it is proposed by trial and error to attempt to establish a new agent. It is not unlikely that success will be secured if a mixed population showing all gradations of susceptibility and resistance is chosen in the hope that a sufficient number of reasonably sensitive individuals will enable the experimentalist to achieve his object.

Latent infections.—The types of infection which are responsible for a heavy mortality, e.g. *Salmonella*, are usually readily recognized. They may seriously interfere with biological research, but at least the investigator should recognize them and may be able to make allowance for their effects. Nevertheless, acute bacterial diseases of this nature sometimes tend to run in cycles and quiescent periods may be encountered when the stock is apparently unaffected. Occasional specific deaths will indicate, however, that infection is merely suppressed and that the disease is kept alive by "carriers" which are particularly dangerous because they are so difficult to detect. The rigorous slaughter of such suspected stock is probably the safest policy.

Equally insidious, although less dramatic in their effects, are the chronic infections, whose existence in "normal" breeding stocks may be quite unsuspected. For example, Sabin (1940) has observed that 80% of some mouse stocks carry pleuropneumonia-like organisms on the nasal mucosa or conjunctiva. Edward (1940) demonstrated that, in untreated mice, these organisms were quite harmless, but if the animals were anaesthetized and inoculated intranasally with any fluid, they might set up small pulmonary lesions, transmissible in series and liable to complicate attempts to isolate new agents. *Streptobacillus moniliformis* is also a common commensal. Wilson Smith (1941) isolated it from cervical abscesses in the Mill Hill stock of guinea-pigs, about 3% of which were affected. It was thought that infection might have been derived from rat-contaminated foodstuffs since Strangeways (1933) had already shown that up to 50% of the normal rat stock might harbour the organism in the naso-pharynx. It is interesting that following the complete elimination of the rat colony and its replacement by a stock which is apparently relatively free from infection, the disease has declined in the guinea-pig and has not reappeared.

The virus diseases which occur in small animals are even more insidious. The importance of latent infections was reviewed in the admirable Presidential Address given by Andrewes (1939) and these conditions confront the breeder with one of his most difficult problems. In mice, for example, infection with the viruses of murine poliomyelitis (Olitsky, 1940), mouse pneumonitis (Nigg, 1942), ectromelia (Marchal, 1930), grey lung virus (Andrewes and Glover, 1945), &c., may be widespread but may, nevertheless, be quite unsuspected. The mild infection of guinea-pigs with salivary gland virus (Cole and Kuttner, 1926), of rabbits with virus III (Rivers and Tillett, 1923) and of pigeons with ornithosis virus (Andrewes and Mills, 1943; Hughes, 1947) are also examples of latency.

A special stimulus may be required to reveal the presence of these agents but they are liable to assume a pathogenic character especially when animals are injected with heterogeneous tissues and fluids particularly by the intranasal route.

In the course of an investigation into porcine influenza an attempt was made to isolate a virus by serial passages of mouse lung from groups of animals receiving infected pig lung intranasally. Two strains of mice were used, one from a self-contained colony and the other derived from a commercial dealer. After three passages at three-day intervals, pulmonary lesions were detected in the close bred mice and were neutralized by specific serum. In the second group small areas of consolidation were seen after three passes and by the fifth passage many of the mice showed extensive lesions similar to those produced by Shope's virus. Serum neutralization tests with anti-influenzal serum failed, however, to inactivate the causal agent. It was eventually established that the mice were carrying ectromelia virus which became highly pneumotropic as a result of serial passage.

On another occasion an attempt was made to isolate a mouse pathogenic agent from throat washings, sputa and lung puncture material from suspected cases of primary atypical pneumonia in man. In both instances serial passages were negative but in a few cases slight lung lesions developed and the agent was identified as a mouse pneumonitis virus of the Nigg type. A latent virus of this type has been revealed in "normal stock" by the intranasal inoculation of sublethal doses of diphtheria toxin.

Most workers are fully alive to the need for great caution when attempting to adapt an infective agent to a heterozygous stock. They realize that the presence of mild infections capable of enhancement in virulence as a result of passage of tissues is so serious that stocks free from such conditions are extremely valuable. Unfortunately it is to be feared that they are all too rare. It is hoped, however, that breeders who possess strains which appear to be unaffected will take rigorous precautions to avoid the introduction of external infections by refraining from introducing fresh stock unless absolutely necessary.

The elimination of latent infections and their continued exclusion present one of the most difficult problems confronting the breeder and much research work will be required to devise satisfactory methods for their detection. Possibly the ultimate solution lies in the development of mutant strains with an increased resistance, but this is a long-term genetical problem requiring much patient work: alternatively, new discoveries in the field of chemotherapy may yield products which are active against these agents. In view of the sensitivity of Nigg virus to sulphadiazine, &c., it would appear possible that a course of drug treatment in breeding stock might achieve the elimination of infection existing in a latent form although, as far as is known, this method has not been tried.

Future developments.—In the past the raising of small animals for research purposes has too frequently been regarded as a side-line. It is true that there are well-organized units associated with large Research Institutes, hospitals or undertakings dealing with biological products, in which the breeding of normal stocks is conducted under proper scientific supervision. In general, these strains are dependable but naturally they can meet only a fraction of the demands of the experimental worker. A high proportion of animals used at the present time is drawn from commercial breeders and dealers, many of whom have no knowledge of the insidious effects of ill-balanced rations on fertility, rates of growth, &c., and are woefully ignorant not only of the dangers of introducing fresh animals without imposing a period of quarantine but also of the steps to be taken to limit outbreaks of disease when they arise.

One feels, therefore, that the quality of animals used for experimental purposes has not kept pace with the general advances in the field of biological research. This may be due in part to the fact that many Institutes are too small to warrant the establishment of an internal breeding unit and the research worker has to turn to commercial sources for his supplies. Even when a breeding colony has been set up, senior members of the staff have often been disinclined to devote sufficient time to the proper supervision of the stock which has been left in the hands of inexperienced and poorly paid attendants. Little improvement can be expected until it is clearly recognized that a high degree of skill and constant vigilance are essential to produce animals of the right type. The capital and maintenance charges of running such establishments are, of course, considerable, and the cost of each individual animal is probably appreciably higher than that obtained in the commercial market under normal conditions. I would add to this that whenever possible normal animals used for breeding should be completely divorced from experimental stock. This implies separate buildings and attendants for each class of animal and rigorous division of the two groups. The safest plan undoubtedly is to remove the breeding stock to a separate self-contained unit at some distance from the laboratory buildings.

It can be claimed that the experience of workers at the National Institute for

Medical Research and at other similar Institutes has shown quite clearly that the provision of a steady supply of suitable stock pays a handsome dividend. Fewer animals are required for critical experiments and the time of the investigator is saved since losses from intercurrent diseases are reduced to a minimum.

During recent years there has been a growing dissatisfaction with the stocks of unknown parentage, particularly in the field of animal nutrition. It is essential in trials of this type that variations due to genetic constitution, intercurrent infections, &c., should not obscure the picture. The case for reducing variability to a minimum has been put aptly by Hutt (1945) who says "when white rats of one strain gain only 14 grammes in five weeks on a diet low in thiamine, and those of another strain over twice as much, the interpretation of results is likely to be confused unless the two strains are in the one laboratory, and the difference, therefore, properly attributed to genetic differences between strain . . . rather than to variations in diets or in environment". This represents a rather extreme case, but the underlying principles are extremely important.

A most useful step was taken by the Conference on the Supply of Experimental Animals. One of the main tasks of the Standing Committee set up by the Conference was to circularize as many suppliers and users of small animals as was possible under wartime conditions. In its Memorandum the Committee forecast a considerable increase in the demand for animals for biological research and stressed that there would be a growing need for "healthy animals" produced under satisfactory conditions. It was strongly urged that in order to control animal supplies it would be necessary to set up some central organization to formulate policy and to act as a clearing house for information. It was suggested that the authority required for such steps should be vested in those Government Departments most intimately concerned with small animal supplies, *viz.* the Medical Research and Agricultural Research Councils, and the Ministry of Supply. This conclusion was reached largely as the result of the replies received from breeders and experimental workers. If mice are taken as an example of the frequency distribution it is found that some of the breeding establishments, both industrial and non-industrial, are breeding animals mainly for their own use although they are able to liberate surplus stocks to other users. There are also a few large-scale trading establishments breeding animals specifically for laboratory use. It is most significant, however, that there is an extensive number of small breeders. Thus if numbers of mice bred were grouped in suitable five- or tenfold multiples, it was found that 32% of the total number of breeders were each producing more than 2,000 mice per annum. The remaining 68% were all commercial units and were producing from 1,000 to 2,000 mice per annum or even less. It was ascertained that a high proportion of these small establishments were distributing stock through dealers. Such animals are often raised in poor surroundings and even if they are free from disease when they leave the breeder, they are liable to acquire infection in the hands of dealers. It was quite clear that the reason for the unsatisfactory conditions was the low price received by the breeder due in part to the profit taken by the middleman. Nevertheless the users are not without blame since so many Institutes fail to recognize that purchases in the cheapest market are not necessarily the most economical in the long run. The output from the large breeding establishments is at present insufficient to meet the demand especially in respect of guinea-pigs. Many Institutes rely, therefore, on the small breeders for their supplies. It is possible that the conditions under which the animals are maintained and distributed might be bettered through discreet propaganda but until the supplier can be guaranteed a satisfactory financial return, there is little hope of effecting a substantial improvement.

It is significant, however, that there is a tendency amongst large users to become self-supporting which will increase as the importance of guaranteed stock becomes more widely accepted and as bigger demands are made for stock for special purposes such as Friedman tests or cancer research.

The Conference recommended that a Committee embracing representatives of all interests concerned should be set up to formulate plans for the co-ordination of supply and demand, for the improvement of existing breeding units and the establishment of fresh centres if considered necessary, and for the development and maintenance of pure line strains, &c. It was also proposed that the collection of the necessary data should be vested in a Central Bureau which would act as a clearing house for information.

The Memorandum prepared by the Conference was submitted to the appropriate Government Departments. After due consideration, the Medical Research Council has agreed to set up an Advisory Committee and Central Bureau and has already taken the necessary steps. When the Bureau is finally established, one of its main tasks will be to renew contact with breeders and users. It is hoped that the breeders will supply full information as to the numbers and types of animals they are raising and thus enable the Bureau to set up a register of breeders—possibly at a later stage a register of accredited breeders. This information will be placed at the disposal of Research Institutes, &c., requiring supplies of suitable experimental animals. The success of the scheme will depend in large measure on the support which the Bureau receives from the two interests, *viz.* the breeder and the user. It is hoped that from time to time meetings will be held with Societies interested in small animal breeding at which the activities of the Bureau will be made known and the views of the biological worker ascertained.

Section of Neurology

President—C. WORSTER-DROUGHT, M.D.

[October 2, 1947]

CLINICAL MEETING AT THE NATIONAL HOSPITAL, QUEEN SQUARE, LONDON, W.C.1.

Dermatomyositis.—J. ST. C. ELKINGTON, M.D.

Mrs. M. G., aged 29, was admitted to St. Thomas's Hospital 25.8.47, complaining of generalized muscular weakness.

History.—Previous health good except for an operation on her thyroid when 10 years of age. Family history—nothing relevant.

Present illness.—Four months before admission she developed a number of small superficial ulcers on her gums and inner aspects of lips and cheeks which coalesced and were very painful. They were accompanied by fever. Two weeks later her toes, arms, legs and back became painful and the limbs became generally weak. The arms were swollen for one week but after a brisk diuresis the swelling subsided. After two months the condition improved but on admission she still experienced difficulty in walking, generalized weakness of arms and legs, shortness of breath and some tendency to regurgitate fluids through the nose on swallowing, and headache.

On examination.—Temperature 98.7° F.; pulse 80; respiration 20. An erythematous rash was present on the butterfly area of the face, the back and front of the neck and the exposed area of the chest and the extensor aspects of the limbs. The affected areas were firm and sclerotic to palpation. There was a variable oedema of the eyelids and face. Numerous small white sclerotic plaques were present on the fingers. The thyroid was not enlarged.

Central nervous system: The cranial nerve functions were normal except for a slightly nasal voice. There was generalized wasting and weakness of the muscles of the limbs and especially those of the trunk with some tenderness on palpation. The arm reflexes were absent, knee and ankle jerks much diminished, abdominal reflexes absent and plantar responses flexor. No sensory disturbance was detected. The gait was "waddling" in character with marked lumbar lordosis and very reminiscent of that of a myopathy.

Investigation.—C.S.F. under normal pressure: 2 cells per c.mm.; Total protein 20 mg.%; Lange 0¹⁰; W.R. negative. Blood W.R. negative. Urine: Creatinine 116 mg./100 c.c.; creatine 46 mg./100 c.c.

Blood: Total protein 7.0; albumin 4.8; globulin 2.2; serum calcium 9.7; phosphorus 3.8; urea 27 mg./100 c.c.; cholesterol 240; alkaline phosphatase 1 unit.

Three successive twenty-four-hourly urine estimations gave:

(1) 1,200 c.c.	Creatinine 855 mg.	Creatine 400 mg.
(2) 1,320 c.c.	Creatinine 935 mg.	Creatine 545 mg.
(3) 1,520 c.c.	Creatinine 918 mg.	Creatine 538 mg.

Dr. F. Parkes Weber remarked that, although Dr. Elkington's case was quite a typical one in the sense that it showed the erythematous manifestations (notably of face) combined with obvious signs of involvement of striped muscle (a biopsy would doubtless have demonstrated degenerative

changes), it was not the most frequent type of dermatomyositis. The most frequent clinical examples constituted one of the most important groups of what Dr. Weber preferred to call "Symptomatic sclerodermas" (Parkes Weber, "Rare Diseases, &c.", London, second edition, 1947, p. 180). They were often diagnosed as examples of symmetrical sclerodermia, though the history of earlier erythematous, oedematous or febrile symptoms should make the diagnosis of dermatomyositis clear. Such cases, under general hygienic conditions with appropriate physical methods of treatment, tended slowly to improve, and occasionally all the sclerodermatous changes cleared up. Acute dermatomyositis, with generalized erythema, oedema and weakness, might prove rapidly fatal, and so also another rare type in young persons with severe myocardial involvement, somewhat suggesting acute rheumatic fever at first sight.

Lesion of the Brain-stem: ? Glioma of Pons and Medulla.—J. ST. C. ELKINGTON, M.D.

Mrs. J. F., aged 36.

History.—Ten months' difficulty in controlling L. leg, seven months' loss of use of L. arm and paralysis of the L. side of the face followed by difficulty in swallowing and talking. Deafness of the L. ear of doubtful duration.

Past history.—An acute illness at the age of 18 described as "sunstroke" characterized by intense occipital and frontal headache associated with sickness and some disturbance of vision. This illness lasted one month and since then the patient has been liable to frontal headaches.

On examination.—Mentally alert and co-operative but of less than average intelligence. Fundi, fields and pupils normal. Slight convergent squint. Complete loss of lateral conjugate deviation of eyes to R. and L. with preservation of upward and downward movements and of convergence. Nystagmus in looking up and down. Wasting of muscles of mastication (L.) with deviation of jaw. Diminution of sensibility to C.W. and P.P. L. forehead. Loss of L. corneal reflex. Loss of sensibility to pain and temperature R. half of face and scalp. Complete lower motor neurone paralysis L. face. Severe diminution of hearing and complete loss of vestibular function L. ear, the R. being then within normal limits. Severe weakness L. half of palate and pharynx, paralysis of L. vocal cord. Wasting and fibrillation L. half of tongue.

Motor functions.—Severe inco-ordination of cerebellar type with very coarse intention tremor in L. arm and leg without appreciable weakness.

Reflexes: Arm-jerks accentuated, knee and ankle jerks accentuated especially on the L. side. Abdominal reflexes absent. Plantars flexor.

Sensation: Loss of sensibility to pain and great diminution of temperature appreciation in the whole R. side of body. Postural sense and sensibility to light touch normal.

Skull normal. General medical examination revealed nothing abnormal.

Investigation.—C.S.F. under normal pressure: Normal in all respects; W.R. negative. X-ray of skull normal. No change in internal auditory meati.

Treated with deep X-ray therapy to region of brain-stem.

Progress.—Condition gradually deteriorating with the exception of the R.-sided analgesia and thermanæsthesia which has cleared up. In the last two weeks has become increasingly deaf in R. ear and vestibular responses are undergoing deterioration.

Thrombosis in the Sagittal Sinus.—J. PURDON MARTIN, M.D.

Mrs. E. M., aged 38.

Developed severe toxæmia in first pregnancy and was delivered on 5.6.47 following surgical induction of labour. Three convulsions occurred within five hours of

delivery, and there was no recovery of consciousness for twenty-four hours. She remained semicomatose for four days with no movement of limbs, and then had two fits which were mostly right-sided. Coma, complete flaccid paralysis and gross œdema followed, but recovery of speech started in twenty-four hours, and now all limbs have recovered and she is able to walk unaided. The paralysis was characterized by relative sparing of the hands and complete sparing of the face, which suggests that it was due to thrombosis of superior cortical veins, and as both sides were affected it is likely that the primary thrombosis was in the superior longitudinal sinus.

Painful Spasms of the Limbs: For Diagnosis.—DENIS BRINTON, F.R.C.P.

Mr. E. L., aged 62. Married ten years. No children.

History.—Deaf for many years (bilateral tympanic perforations). Psoriasis. No history of V.D. or head injury.

Present complaint.—Since August 1944 has had attacks of severe cramp-like pains in the limbs. Sometimes has trembled violently and fallen over. Tonic spasm usually begins in right leg, travels to right arm then left arm and left leg. Cries out with pain but no convulsions or loss of consciousness. Three years ago vision began to fail, especially in left eye. In past year has had "pins and needles" in both arms. Lately some stress-incontinence. Now has 10 to 20 attacks a day. Duration less than one minute.

On examination.—No obvious intellectual or emotional defect. V.A.R. 6/5 (corrected). Right disc pale. V.A.L.—hand movements only. Left primary optic atrophy and central scotoma. Left pupil reacts sluggishly to light. Limbs—no gross weakness but slight spasticity, ataxic gait, brisk tendon reflexes and doubtful extensor plantars. Sensation normal. Blood-pressure 110/74. C.S.F. normal. W.R. negative in C.S.F. and blood.

Calcified Aneurysm of Left Internal Carotid Artery (With Proptosis and Optic Atrophy).—S. P. MEADOWS, M.D.

L. W., male, aged 58.

History.—Seventeen years ago the patient developed severe pain in the left eye, followed, a few days later, by prominence of the left eye, squint and diplopia. The pain soon disappeared, but the proptosis and squint remained. Eight years ago he had a temporary recurrence of the severe ocular pain, and soon afterwards noticed that his left eye was almost blind. He has had two further attacks of severe pain in the left eye during the past year, lasting some weeks on each occasion, with vomiting, but with no dramatic change in the eye, and no loss of consciousness. During the last attack at Easter 1947 he noticed a sensation of "pins and needles" in the forehead and temple on the left side. There has also been increasing bilateral deafness during the past ten years.

On examination.—Marked left proptosis (about 4 mm.), but no pulsation. No bruit audible on auscultation of skull or eye. The left eye is blind, and the left optic fundus shows "primary" optic atrophy. Ocular movements of left eye very limited in all directions, except depression, which is almost full. Slight left ptosis. Left pupil of moderate size, fixed to direct light, but reacts slightly consensually. Left corneal reflex absent, and cutaneous sensation impaired over distribution of first division of left sensory fifth nerve. Bilateral deafness. Plantar responses extensor. No other abnormal signs in C.N.S. B.P. 120/85.

changes), it was not the most frequent type of dermatomyositis. The most frequent clinical examples constituted one of the most important groups of what Dr. Weber preferred to call "Symptomatic sclerodermas" (Parkes Weber, "Rare Diseases, &c.", London, second edition, 1947, p. 180). They were often diagnosed as examples of symmetrical scleroderma, though the history of earlier erythematous, œdematous or febrile symptoms should make the diagnosis of dermatomyositis clear. Such cases, under general hygienic conditions with appropriate physical methods of treatment, tended slowly to improve, and occasionally all the sclerodermatous changes cleared up. Acute dermatomyositis, with generalized erythema, œdema and weakness, might prove rapidly fatal, and so also another rare type in young persons with severe myocardial involvement, somewhat suggesting acute rheumatic fever at first sight.

Lesion of the Brain-stem: ? Glioma of Pons and Medulla.—J. ST. C. ELKINGTON, M.D.

Mrs. J. F., aged 36.

History.—Ten months' difficulty in controlling L. leg, seven months' loss of use of L. arm and paralysis of the L. side of the face followed by difficulty in swallowing and talking. Deafness of the L. ear of doubtful duration.

Past history.—An acute illness at the age of 18 described as "sunstroke" characterized by intense occipital and frontal headache associated with sickness and some disturbance of vision. This illness lasted one month and since then the patient has been liable to frontal headaches.

On examination.—Mentally alert and co-operative but of less than average intelligence. Fundi, fields and pupils normal. Slight convergent squint. Complete loss of lateral conjugate deviation of eyes to R. and L. with preservation of upward and downward movements and of convergence. Nystagmus in looking up and down. Wasting of muscles of mastication (L.) with deviation of jaw. Diminution of sensibility to C.W. and P.P. L. forehead. Loss of L. corneal reflex. Loss of sensibility to pain and temperature R. half of face and scalp. Complete lower motor neurone paralysis L. face. Severe diminution of hearing and complete loss of vestibular function L. ear, the R. being then within normal limits. Severe weakness L. half of palate and pharynx, paralysis of L. vocal cord. Wasting and fibrillation L. half of tongue.

Motor functions.—Severe inco-ordination of cerebellar type with very coarse intention tremor in L. arm and leg without appreciable weakness.

Reflexes: Arm-jerks accentuated, knee and ankle jerks accentuated especially on the L. side. Abdominal reflexes absent. Plantars flexor.

Sensation: Loss of sensibility to pain and great diminution of temperature appreciation in the whole R. side of body. Postural sense and sensibility to light touch normal.

Skull normal. General medical examination revealed nothing abnormal.

Investigation.—C.S.F. under normal pressure: Normal in all respects; W.R. negative. X-ray of skull normal. No change in internal auditory meati.

Treated with deep X-ray therapy to region of brain-stem.

Progress.—Condition gradually deteriorating with the exception of the R.-sided analgesia and thermanæsthesia which has cleared up. In the last two weeks has become increasingly deaf in R. ear and vestibular responses are undergoing deterioration.

Thrombosis in the Sagittal Sinus.—J. PURDON MARTIN, M.D.

Mrs. E. M., aged 38.

Developed severe toxæmia in first pregnancy and was delivered on 5.6.47 following surgical induction of labour. Three convulsions occurred within five hours of

Amyotrophy—Syphilitic.—COLIN EDWARDS, M.R.C.P.

Male, aged 50.

History.—Weakness of right fingers began insidiously in 1939. A year later he noted wasting and twitching of the right hand and arm muscles. Weakness of right leg followed with subsequent wasting.

1942: Admitted to hospital. C.S.F. analysis normal except for total protein of 60 mg.%. Blood W.R. positive. Impaired pain sensation was found over the right shoulder, arm and chest covering an area from C.4 to T.5 and considerable loss of tendo Achillis pain sensation together with wasting and fasciculation in the muscles of the right arm and leg, but there was no evidence of other sensory loss or of pyramidal involvement.

He was given intensive antisymphilitic treatment (chiefly with bismuth) for more than a year and then ceased to attend hospital until sent in recent months for review. He says that his condition has been quite stationary for the past two years.

Present condition.—There is now marked wasting of right hand, arm and shoulder girdle muscles with fasciculation there and in the other three limbs. Right leg wasted, right thigh slightly so. Tendon-jerks diminished in wasted limbs but only absent in markedly atrophic areas; left ankle-jerk absent, right very sluggish. Plantar reflexes flexor. Hypoalgesia to pin-prick over right segmental areas C.3 to C.8 and over the whole right lower limb. Loss of tendo Achillis pain sensation. Sensation otherwise unimpaired. Leukoplakia of the tongue is the only other abnormal finding.

Blood W.R. weakly positive but Kahn is definitely positive. C.S.F. normal except for protein of 60 mg.% and slight excess of globulin.

The President considered that the diagnosis was undoubtedly one of syphilitic amyotrophy on: (1) The relatively long history—eight years; (2) the fact that the condition had remained quiescent for at least the past two years; (3) the sensory abnormalities; (4) the fact that the amyotrophy is hypotonic rather than hypertonic; and (5) the positive Wassermann reaction in the blood. In many cases the cerebrospinal fluid shows no abnormality. Dr. Purdon Martin in 1924 had drawn attention to the predominance of the hypotonic type of muscular atrophy—rather than the hypertonic type—in syphilitic amyotrophy. A somewhat similar case was recalled by the President. This was a man who developed an amyotrophy affecting the right arm two years after the W.R.s had become negative; two years later he developed a Charcot arthropathy of the right shoulder-joint. Consequently in some cases even the blood W.R. may be found negative. Another example was that of a woman—the wife of a man with *tabes dorsalis*—who developed a muscular atrophy of hypotonic type affecting both arms and legs. She was first seen at the age of 50 and five years after the onset of muscular atrophy when the W.R. in both blood and cerebrospinal fluid was negative. She continued for a further twelve years without obvious deterioration (total course seventeen years) when she died from an intercurrent malady.

Spondylolisthesis with Cauda Equina Lesion.—N. G. HULBERT, M.D.

W. C., male, aged 69.

Present complaint.—Pain in the back and weakness of the legs.

History.—1940: At the age of 62, gradual onset of “pins and needles” in right leg which soon after became weak. In 1941, his left leg became affected, leading to difficulty in walking. He was admitted to a hospital, where apparently a diagnosis of motor neurone degeneration was considered. The legs gradually became weaker and he was admitted to the West End Hospital for Nervous Diseases in May 1944.

On examination.—His gait was unsteady, on a widened base, and he needed the support of a stick. Loss of power in all muscles below the knees but especially those of calf, with some wasting and hypotonia. Knee-jerks present and equal but ankle-jerks absent. Plantar reflexes flexor and abdominals present. Reduced sensa-

FIG. 1.

Calcified aneurysm left internal carotid artery with ring shadow above sella.

X-ray skull.—Large calcified ring shadow to the left of the sella, 4.5 cm. long by 3 cm. high. The margins of the left optic foramen are not visible, presumably due to pressure, and there is decalcification of the lesser wing of the sphenoid (fig. 1).

Percutaneous arteriography (Uriodone).—Appearances suggest a block of the left internal carotid artery just distal to the bifurcation of the common carotid artery. Although the needle appears to be in the internal carotid artery the contrast medium has run back and filled the external carotid artery.

This aneurysm probably originated in the intracavernous portion of the carotid artery, and rupture has been prevented by the dural sac of the sinus. The arteriographic findings suggest that the aneurysm has thrombosed (see similar calcified aneurysm, Meadows, S. P. (1934) *Proc. R. Soc. Med.*, 27, 1355).

Multiple Congenital Abnormalities.—DENIS WILLIAMS, M.D.

P. S., male, aged 14 years.

A case of maldevelopment of osseous, muscular, and subcutaneous tissue with central nervous system dysfunction as shown by intellectual impairment and dysphasia. There are electro-encephalographic and pneumo-encephalographic changes.

History.—The patient was apparently well until 11 months of age when he had measles followed by a constant right internal strabismus, a productive cough and radiographic evidence of pulmonary consolidation for two years. At the age of 2 years it was noticed that he had a deformity of the skull and scoliosis and that his joints were enlarged and limited in movement. He could not walk until the age of 3, after which he began to sustain closed fractures with minimal trauma. He had ten of these by the age of 11. He is ambidextrous but uses the left hand rather more than the right. He has had a slurring dysarthria and inco-ordination of fine movements since the age of 5 years. At the age of 8 to 10 it was found that he could not read or tell the time as well as the average child. He can handle figures visually or on auditory description; his most selective disability lies in comprehension of written symbols. No family history of similar complaint.

Dr. F. Parkes Weber suggested that the heading of Dr. Denis Williams's very interesting case might be altered from "Multiple Congenital Abnormalities" to "Amyoplasia (Hypomyoplasia, or Dysmyoplasia) Congenita, with Associated Abnormalities". The abnormalities associated with amyoplasia (Sheldon) differed widely in different cases. The association in this case might be termed "Denis Williams's type", whereas that in Dr. R. N. Herson's case (*Lancet*, 1947 (ii), 491) might be called "Herson's type". The secondary sclerotic process in the soft parts of the upper limbs in Dr. Williams's case, and the relatively slight secondary grasping posture of the hands, were insufficient to justify the term "Arthrogryposis multiplex congenita" (Stern). In regard to the generalized muscular defect the appearance of the whole thorax was very striking.

Clinical Section

President—G. E. VILVANDRÉ

[November 14, 1947]

Mikulicz's Syndrome.—F. L. KING-LEWIS, M.R.C.S., L.R.C.P., D.C.H.

Mrs. F., widow, aged 57.

History.—She has had intermittent swelling of both parotid glands, increasing dryness of mouth and a sore tongue for the past three years. On one occasion a small gritty particle was felt in Stenson's duct and later this passed into the mouth. For the past year she has had recurrent attacks of conjunctivitis and blepharitis, and more recently has noticed an inability to shed tears. There is nothing else significant in her past history, and no family history of any similar condition.

On examination.—There is chronic slight enlargement of both parotid glands and the submandibular glands are also palpable. Mr. J. H. Daggart has examined her eyes and reports the presence of keratoconjunctivitis sicca. Heart, lungs and abdomen normal. The liver and spleen not felt; no involvement of lymphatic glands. The blood-pressure is 180/95 and the urine is clear.

Investigations.—X-rays of the parotid glands show multiple small calculi; no sign of calculus in the ducts. X-rays of the lungs and hands show no abnormal changes.

Blood-count (November 1947).—R.B.C. 4,900,000; Hb 66% (Haldane); C.I. 0.67; W.B.C. 7,900, with normal differential count.

Treatment.—A culture was taken from the opening of Stenson's duct and penicillin-sensitive pneumococci were grown. A course of penicillin was therefore prescribed and 300,000 units in oil and beeswax were given, intramuscularly, twice daily for nine days.

The patient developed a severe urticaria at the end of this period. Sensitivity to potassium iodide was also shown on one occasion when this drug had been prescribed. A course of short-wave diathermy was administered to the parotid glands and although there appeared to be an improvement for a time this was not maintained.

The present treatment is entirely palliative.

Comment.—Mikulicz's disease proper is confined to cases in which there is swelling of the lacrimal and salivary glands and in which there is no involvement of the lymphatic system and a normal blood picture. It is probable, however, that many examples of Mikulicz's disease published in the literature have subsequently developed such changes.

The causes of Mikulicz's syndrome can be grouped under two headings: (1) The reticulosos and reticulo-sarcomata. (2) The granulomata.

Dr. F. Parkes Weber regarded the case as one of Sjögren's syndrome, that is to say, keratoconjunctivitis sicca, with swelling of the parotid salivary glands and dryness of the mouth as striking (though non-ocular) features. Such symptoms, at all events in early stages, might be intermittent or remittent. In his paper on the non-ocular features of Sjögren's syndrome (*Brit. J. Ophthalm.*, 1945, 29, 299) Dr. Weber had not alluded to any case like the present one, with minute salivary calculi as a (? secondary) complication. From the symptomatic point of view Dr. King-Lewis's case might of course also be termed one of Mikulicz's syndrome, though not Mikulicz's disease.

tion to light touch and pin-prick over buttocks and back of thighs, extending nearly to popliteal space on left and half-way down thigh on right. Tendo Achillis analgesia, and vibration sense much reduced in legs. Some hesitancy of micturition: anal and bulbo-cavernosus reflexes both present. Anus slightly patulous. Heart normal with blood-pressure 140/80.

X-rays showed pronounced spondylolisthesis, the dorsum of sacrum being almost at right angles to axis of spinal column; fifth lumbar vertebra wedge-shaped with apex posteriorly. The cerebrospinal fluid showed no abnormality, with pressure 85 mm., total protein 35 mg.%. W.R. negative in cerebrospinal fluid and blood. A myelography with lipiodol showed the lipiodol column to end at the upper border of the first sacral segment.

On May 30, 1944, laminectomy (Mr. G. C. Knight) was performed. The fifth lumbar vertebra lay about 1 cm. deeper from the surface than its normal line. It was displaced quite considerably in relation to the fourth lumbar vertebra, but it was only slightly depressed and rotated in relation to the first sacral segment, the maximum displacement being at the upper border of the lamina. The laminae of the fifth lumbar and first sacral were excised. The theca seemed to be kinked on the posterior aspect beneath the fifth lumbar lamina at its junction with the first sacral segment, but Mr. Knight was not convinced that this really caused compression, as the anterior face of the neural canal was entirely smooth, without any projection of the vertebral bodies which might distort its lumen. There was a considerable pad of fat beneath the junction of the fourth and fifth lumbar vertebrae.

The patient's condition has remained much the same excepting that the calf muscles have become weaker and more atonic. November 1946: The cerebrospinal fluid again showed no abnormality. Lumbosacral support gives no apparent benefit.

Comment.—First, was the lesion, as seems probable, one of the cauda equina rather than of the conus medullaris; second, was the gross spondylolisthesis the cause of the cauda equina lesion, or if it were coincidental what alternative cause could be assigned for the condition? It was suggested that the spondylolisthesis might be causative.

In reply to a question raised regarding possible involvement of the fourth and fifth lumbar roots, as shown by the wasting of the gluteal muscles, it might be suggested that the gross displacement shown on the X-rays could well cause compression or tension of the fifth lumbar root, while the first and second sacral roots are also concerned in the nerve supply of the gluteal muscles.

In reply to a further question there was no history of trauma.

POSTSCRIPT. Since the case was shown, further examinations on the X-ray tilting table have suggested some narrowing of the lipiodol column in the region of the first lumbar vertebra, and a further laminectomy is contemplated.

This case was shown on account of the uncommon nature of the gastric tumour and because it demonstrated the ease with which resections involving the uppermost part of the stomach can be performed when using an abdomino-thoracic incision. This approach is well tolerated even by elderly patients and does not necessarily entail a more complicated convalescence than a purely abdominal intervention.

Severe Diabetic Neuropathy with Right Phrenic Palsy.—E. MONTUSCHI, M.D., and G. MELTON, M.D.

N. H., male, aged 57.

Past history and family history.—Nothing relevant. Married, with two sons.

History of present complaint.—Glycosuria discovered in 1943. Stabilized with diet and insulin at Prince of Wales Hospital, Tottenham. In November 1944 required higher doses of insulin—40 units Z.P.I. and 40 units S.I. November 1945: Onset of cramps in legs and weakness in both legs and right arm. Much worse in March 1946, with severe weakness and dimness of vision, loss of weight and anorexia. No bladder dysfunction. Admitted to Prince of Wales Hospital in May 1946. Findings as follows:

Diabetic retinitis in right eye. Wasting of shoulder-girdle muscles on the right. Severe wasting of muscles of both legs, with vasomotor changes in the feet. Bilateral foot drop.

Investigations.—Blood-count normal; diabetes apparently well controlled. Wassermann negative. C.S.F. contained 325 mg. of protein and no excess of cells. Skiagram of chest normal. E.C.G. normal.

Transferred to Northern Hospital on 19.6.46. Progress has been very slow, but good, and he can now walk with the aid of toe springs and sticks. Slight paresthesiae in right upper limb, with uncertainty in writing. No sphincter disturbances, but impotence. The requirements of insulin have diminished. Now on S.I., 30 and 44 units daily, with glycosuria well controlled.

On examination.—Amblyopia right eye, right pupil smaller than left; reacts sluggishly to light but well to convergence, and dilates only half-way with atropine. Marked neuro-retinopathy on the right, less marked on the left. No wasting of shoulder girdle. Good motor power in both upper limbs, with no demonstrable sensory loss. Supinator, biceps and triceps jerks present but weaker on the right side. Superficial abdominal reflexes present. Lower limbs—good glutei. Some wasting but fair power of extensors in both thighs, better on the right. Severe wasting of muscles of leg on both sides, with complete foot drop. Right knee-jerk present, left absent. Ankle-jerks absent. Plantar reflexes not obtained. Complete sensory loss over distal part of the feet. Sensory loss less marked over lateral aspect of legs. Glossy skin, vasomotor and sudomotor palsy over the feet and distal part of the legs. C.V.S.—Heart normal, B.P. 115/90, dorsalis pedis and posterior tibial arteries easily felt on both sides. Respiratory system.—Poor air entry and diminished respiratory excursion at the right base.

Investigations.—Blood-count normal. Fractional test meal shows high acidity curve. Blood sugar estimations and urinalysis charts show moderately severe diabetes well controlled by insulin. Blood cholesterol 208 mg. %. W.R. negative in the blood and C.S.F. Repeated investigations of C.S.F. show raised protein, now 60 mg. %, Lange's curve normal, pressures normal, and Queckenstedt's test shows no spinal block. Skiagrams of chest from July 1947 show paralysis of right dome of diaphragm, with slight paradoxical movement. Screenings confirmed by double exposure film on 30.9.47. Skiagram of cervical spine showed no abnormality.

Comments by Dr. E. Montuschi.—Diabetic neuropathy of the severity of the present case has been repeatedly described in the literature, but a marked polyradiculitis, with raised protein in the C.S.F. and an Argyll-Robertson pupil, are not common. We can find no reference to phrenic palsy in diabetic polyneuritis, although it has been described in alcoholic and other toxic neuropathies. There are no clues to any other aetiological agent but diabetes in our patient.

Polycythæmia Vera. Hypertensive Heart Disease. Erythromelalgia Syndrome and Osteoarthropathy in the Right Leg.—G. MELTON, M.D., and E. MONTUSCHI, M.D.

Housewife, aged 58. Symptoms of polycythæmia and hypertension first appeared during 1938. Frequent venesections at London Hospital in 1939. Symptoms of circulatory failure for past two years.

October 1946: Complained of increasing pain, burning, sweating and swelling in right leg, particularly when walking. Admitted to Northern Hospital in May 1947.

Leiomyosarcoma of Stomach. Thoracico-abdominal Gastrectomy.—FRANK FORTY, F.R.C.S.

H. W. P., male, aged 66.

History.—For the past two months the patient had noticed that his food seemed to stick at the level of the lower end of the sternum. Swallowing was difficult and painful. He had lost some weight.

On examination.—No abnormality was found.

Barium swallow.—Barium was held up at the cardia. There was slight dilatation of the œsophagus. There was a large filling defect between the lower end of the œsophagus and the barium-filled body of the stomach. The appearances indicated a large proliferative growth of the cardia.

Operation (22.5.47).—Regional block plus gas, oxygen and ether anaesthesia. Exploration of the abdomen through an upper left paramedian incision disclosed that the growth was mobile and that there were no metastases. The incision was extended transversely through the left rectus muscle and the chest opened along the eighth left intercostal space, the costal margin divided and the diaphragm split. The upper half of the stomach and lowest inch of the œsophagus were resected. The œsophagus was anastomosed to the body of the stomach in the left pleural cavity. The chest was drained through the ninth interspace and the incision closed.

Post-operative progress.—There were no complications. A barium swallow one month after operation passed down the œsophagus without delay or difficulty and there was no obstruction at the site of the anastomosis. The patient left hospital five weeks after operation.

The specimen.—A sessile, slightly lobulated tumour occupies the fundus of the stomach and projects into the lumen. The mucosa over the tumour is smooth and not ulcerated. The margins of the tumour are well defined (fig. 1).

FIG. 1.

Photograph of operative specimen showing the tumour. The rubber tube marks the junction of the œsophagus with the stomach.

Histological report.—Tumour composed of fasciculæ of spindle-shaped cells separated by thin layers of collagenous tissue. The muscle immediately underlying the mucosa is compressed but not invaded. Within the tumour there are strands of cells indistinguishable from ordinary smooth muscle and the close connexion of the tumour cells with these suggests that they arise from them. The irregular nuclear size and hyperchromatism of many of the neoplastic cells suggest a degree of malignancy although mitosis is infrequent (fig. 2) Diagnosis: Leiomyosarcoma of low-grade malignancy.

×90

×420

FIG. 2.—Photomicrographs of the tumour. See description in text.

II.—Trans thoracic Vagal Section for ? Recurrent Anastomotic Ulcer.

Mr. H., aged 54.

History.—Symptoms of duodenal ulcer commenced in 1929, when aged 38, and continued until 1944, when a gastro-enterostomy was done at another hospital. The pain returned two weeks after operation. Severe diarrhoea developed in April 1947, accompanied by loss of weight. In July 1947 laparotomy showed a gastro-jejuno-colic fistula. Partial colectomy and partial gastrectomy with posterior gastro-jejunostomy were performed.

22.10.47: Patient readmitted complaining of recurrence of pain.

Night secretion test showed abundant free acid in every specimen except one. Histamine test and insulin test showed a similar high response. On 28.10.47 gastroscopy—no anastomotic ulcer seen. However, it was felt that this patient might well be going on to form another anastomotic ulcer with its attendant dangers.

5.11.47: Trans thoracic vagal section was performed through the left eighth intercostal space, dividing the ninth rib posteriorly. The left and right vagi were ligated proximally and 1½ in. of each were removed down to the oesophageal hiatus.

Post-operative convalescence was uneventful.

24.11.47: Night secretion test showed complete achlorhydria. There was slight response to histamine showing the presence of acid-producing cells in the stomach, but insulin test gave a negative response, indicating complete section of the vagi.

Mr. R. C. B. Ledlie said that these cases illustrated the profound effect produced on the gastric secretion soon after vagus resection. The first case showed the value of estimating the night secretion and the insulin test in determining whether the vagus resection was complete. An abdominothoracic approach had been employed to overcome the anticipated technical difficulties from adhesions in dealing with a gastro-jejuno-colic fistula after three previous gastrectomies. It was of interest to note that the pleural cavity did not become infected although the operation necessitated closure of an opening in the colon. This might well have been due to the use of sulphasuxidine and penicillin.

Cloquet's Hernia.—H. FREEMAN, F.R.C.S.

H. C., a male, developed a large right inguinal hernia following an operation for appendicitis in 1933. In 1941 he noticed a small globular swelling in the left groin which gradually became bigger yet remained painless. The swelling extended into the upper part of the thigh; he can push it upwards until it disappears, and it seems to be controlled by a truss.

Cloquet's hernia, or pectineal hernia as it is sometimes called, was first described in 1777 by Callinson and later by Cloquet in 1817. It is a variety of femoral hernia, but instead of descending from the femoral canal through the saphenous opening and cribriform fascia, Cloquet's hernia passes more medially, not through the saphenous opening, but over the pectineus muscle through the loose connective tissue and into the thigh, where it is separated from the skin by subcutaneous tissue only and may even descend as far as the knee-joint.

Mr. Duncan Fitzwilliams said that Cloquet's hernia was a rare condition. In this case it was replaced with remarkable ease, but he thought he could feel a small finger of omentum which was adherent low down in the sac, which did not reduce and which caused re-descent on the slightest exertion.

Malignant Melanoma of Eyelid with Secondary Deposits in Regional Lymphatic Nodes.— REGINALD A. KING, F.R.C.S.

Mrs. E. G., aged 45.

Four years ago a pigmented mole on the left lower eyelid began to enlarge. It was treated by silver nitrate cautery by her doctor.

July 1947: A recurrence on the same eyelid was partially removed for section by an ophthalmologist. Pathological report: Malignant melanoma.

August 1947: Wide excision of lower eyelid with plastic repair.

November 1947: Pre-auricular and post-auricular nodes enlarged and increasing. Small nodule of growth on lower lid. Abdomen and chest normal. X-rays of chest normal.

Suggested treatment.—Excision of lower eyelid with enlarged lymph nodes and intervening lymphatics *en bloc*. Facial hypoglossal nerve anastomosis.

Mr. Duncan Fitzwilliams said that he thought the idea of a block dissection of the growth, the lymphatics across the cheek, and the glands of the region was not a wise procedure. Theoretically it was correct perhaps but this procedure was not followed in the case of cancer of the tongue or of melanotic growths—for instance in the foot. It was considered enough to make a wide excision of

On examination.—Clinical picture of polycythæmia vera with typical appearance, gross splenomegaly and characteristic blood picture. There were also signs of hypertensive cardiac failure, mainly left-sided.

Right leg larger than left; characteristic appearance of erythromelalgia, being warmer and redder than the left; sweating of right foot with marked pulsation of the dorsalis pedis and posterior tibial arteries. The skin temperatures confirmed the warmer state of the right leg.

X-rays: Right leg—tibia, fibula, and metatarsals were broadened and showed periosteal thickening characteristic of osteo-arthritis. X-ray of chest shows marked cardiac enlargement and signs of extensive pulmonary congestion at both lung bases.

Blood-count.—R.B.C. 8,400,000; Hb 156%; W.B.C. 23,700; Polys. 95%. No primitive cells; platelets 1,750,000.

Progress.—Deep X-ray therapy June and July. Blood-count on 9.7.47: R.B.C. 7,300,000; Hb 140%; W.B.C. 21,000; platelets 285,000. Spleen markedly smaller; below this could be felt a mass which, on intravenous pyelography, was confirmed as being the left kidney. The pyelography shadow was normal. There had been albuminuria, together with a *B. coli* urinary infection, in July, which cleared up on sulphonamide therapy. Cardiac failure abated. Symptoms and signs in the right leg much improved and there is now no evidence of erythromelalgia. However, the X-ray appearances are unchanged.

Comment.—Erythromelalgia has been frequently described as a complication of polycythæmia vera, and on several occasions it has been noted as being unilateral, as in the above case. We have been unable to find any record in the literature of unilateral osteo-arthritis associated with erythromelalgia as a complication of polycythæmia vera. We consider it probable that the osteo-arthritis has arisen as a result of the chronic pulmonary stasis with secondary infection in the lungs, and that the localization in the right leg was probably determined by the abnormal peripheral vascular changes in the limb.

Dr. F. Parkes Weber, in discussing the erythromelalgia-like syndrome in the right lower limb (which had already almost subsided), referred to the case of a Rumanian woman, aged 36, with typical splenomegalic polycythemia, who had recovered from an acute erythromelalgia-like attack in the feet (chiefly the left foot). She also had arterial hypertonia (F. P. Weber, *Med.-Chir. Trans.*, London, 1905, 88, 191).

Dr. Weber did not think that the X-ray appearances in the present patient's right leg were like the typical symmetrical changes in true cases of pulmonary osteo-arthritis, but he drew attention to H. Batty Shaw's account of changes of the kind in heart disease—compare Batty Shaw and Stanley Melville, *Proc. R. Soc. Med.*, 1917, 10, Clin. Sect., page 8; Batty Shaw and R. H. Cooper, *Trans. Clin. Soc., Lond.*, 1907, 40, 259; L. F. Barker, *Intern. Clinics*, 40th series, 1930, 3, 54.

[December 12, 1947]

TWO CASES SHOWN BY D. P. CHOYCE, F.R.C.S., FOR R. C. B. LEDLIE, F.R.C.S.

I.—Abdominothoracic Approach to Recurrent Gastro-Jejuno-Colic Fistula with Section of Vagi.

Mr. E., aged 53.

History.—1935: Perforated duodenal ulcer. 1936: Polya type partial gastrectomy for cicatrized duodenal ulcer. 1938: Operation for anastomotic ulcer. Further strip of stomach removed and new anastomosis made. 1941: Another anastomotic ulcer adherent to colon. Fistula undone and anterior gastro-jejunostomy performed. Left subphrenic abscess and left empyema had to be drained during convalescence.

1941–1946: Epigastric pain after meals continued. One hæmatemesis in 1946.

September 1947: Readmitted complaining of epigastric pain and recent diarrhœa.

1.10.47: Right transthoracic vagal section.

19.10.47: Patient losing ground. Night secretion, histamine and insulin tests showed abundant free acid, indicating that section of the vagi had not been complete.

29.10.47: *Final operation*—abdominothoracic approach. Gastro-jejunocolic fistula separated into components. Holes in colon and jejunum closed. Anterior gastro-jejunostomy performed. One and a half inches of vagi excised at œsophageal hiatus.

21.11.47: Good recovery. Night secretion and insulin tests show almost complete achlorhydria, indicating complete section of the vagi.

Section of Dermatology

President—J. E. M. WIGLEY, F.R.C.P.

[October 16, 1947]

Epidermolysis Bullosa Acquisita.—H. W. BARBER, F.R.C.P.

Male, aged 42. Agricultural labourer. Married with one normal child aged 11. Three brothers and two sisters alive and well. One sister died in childbirth. No history of any comparable disease in the family.

Eruption appeared four and a half years ago as "small blisters" on lower abdomen. Other parts including buccal mucosa affected later. Lesions dried into scabs, leaving "scars" on which new blisters appeared after traumatism. At that time trauma did not produce lesions on normal skin. The condition was diagnosed as *pemphigus* and he was admitted to the local hospital, where the skin healed, but relapsed on some areas soon after discharge.

16.8.43: First seen by me. Diagnosis: Dermatitis herpetiformis with buccal lesions. Characteristically grouped urticarial papules and bullæ were then present. Cleared temporarily with sulphapyridine. Seen again 4.12.44. Grouped lesions still present and single bullæ of some size. Diagnosed as transitional case between dermatitis herpetiformis and pemphigus. No suggestion then of epidermolysis bullosa, nor when in Guy's Hospital 11.8.45–1.11.45. Treated with blood transfusions, sulphapyridine, and fourteen three-day courses of stovarsol. Discharged greatly improved. Seen again 25.7.46. In the meantime iodide had been given and had apparently provoked new lesions.

14.9.47: Readmitted to Guy's Hospital. Had done no work for two years. Clinical picture completely changed. Raw or crusted lesions, some of considerable size, chiefly at pressure-points over bony prominences and on folds of skin liable to tension, e.g. axillæ and antecubital fossæ. Skin of hands and feet atrophic and papyraceous with bullæ or their remains. Buccal mucous membrane affected by recurrent blisters leaving painful raw areas. Diagnosis of *epidermolysis bullosa acquisita* made. The majority of bullæ are subepidermal, others apparently under the stratum corneum.

Investigations.—Urine: No albumin or sugar. Calcium oxalate crystals.

Blood-counts.—15.9.47: Hb 72%; R.B.C. 4,200,000 per c.mm.; C.I. 0.86; W.B.C. 10,000 per c.mm. Differential count: Polys. 64%, eosinos. 9%, basos. 1%, lymphos. 24%, monos. 2%. 1.10.47: W.B.C. 8,400 per c.mm. Polys. 70%, eosinos. 4%, basos. 1%, lymphos. 22%, monos. 3%. Serum chloride 268 mg.%. Serum sodium 360 mg.%. Urinary excretion of chloride within normal limits.

Biopsy.—The skin shows separation of the epidermis from the dermis by œdema fluid and is devoid of inflammatory disease. Elastic fibres are scanty or absent below the bullæ.

the growth and to remove the glands of the region; the lymphatic vessels were left alone. Most people recognized that inadequate treatment of the small growth by the cautery usually only stimulated the growth and was like stirring up a wasp's nest with a stick. He thought in this case the excision should be wide and it might be found that this had to include excision of the eye.

Diabetic Neuropathy and Hepatomegaly.—R. N. HERSON, M.B. (introduced by Dr. N. LLOYD RUSBY).

H. N., male, aged 64.

First seen February 1947. Sugar first found in urine ten years previously, but he had not kept to a diet or received insulin regularly.

On admission.—Urine loaded with sugar, acetone+. Immature cataracts; pupils did not react to light or accommodation. Arteries thickened, B.P. 180/100. Left foot gangrenous. Knee and ankle jerks absent. Chronic *B. coli* infection, resistant to sulphonamides. Blood sugar controlled on a diet of 200 grammes carbohydrate, 80 grammes protein, 80 grammes fat, and 25 units soluble insulin morning and evening. The gangrene was treated locally and with intramuscular penicillin. He was discharged at the end of August.

Readmitted in October, with bilateral ptosis which had developed suddenly after three weeks' severe continuous frontal headache. Epigastric discomfort and flatulent dyspepsia. Sallow complexion, slight yellow discoloration of sclerae. Liver 3 fingerbreadths below costal margin, smooth, firm and not tender.

Eye movements almost absent. Pupils small and fixed. Corneal reflexes present. Remainder of cranial nerves intact. Right biceps-jerk present, other arm-jerks absent. Upper abdominal reflexes obtained, not lower. No weakness or inco-ordination of lower limbs. Knee and ankle jerks absent. Right plantar response equivocal, left could not be elicited because of deformity of foot. No loss of appreciation of touch but pin-prick could not be felt below middle of legs. Responses to heat and cold irregular. Complete loss of vibration sense in legs, no loss of position sense. Dr. Blake Pritchard considered the dissociated sensory loss could only be explained on the basis of a central lesion, the oculomotor palsies and loss of tendon-jerks being consistent with diabetic neuropathy.

Investigations.—Urine: Alkaline; protein 0.012%, sugar varying; urobilin, slight excess; bile pigments trace; bile salts nil; a few erythrocytes and a large number of leucocytes. Culture: *B. coli*.

Blood: Hb 90%; R.B.C. 4,750,000; M.C.V. 86.3 c. μ ., W.B.C. 12,300 (polys. 54%, lymphos. 31%, monos. 12%, eosinos. 2%). Blood urea 39 mg.%. Blood W.R. and Kahn negative. Blood sugar curve: Before sugar 364 mg. per 100 c.c., after thirty minutes 400; sixty minutes 570; ninety minutes 500.

C.S.F. Clear, colourless; protein 90 mg.%, chlorides 730 mg.%.

22.10.47: Van den Bergh, direct weakly positive in half a minute, indirect 1.7 mg.%. Total protein 6.87, albumin 2.76, globulin 4.11 grammes%. A/G ratio 1/1.5. Alkaline phosphatase 72 units, gold test + 3, thymol turbidity 14 units. Serum cholesterol 285 mg.%.

Test meal: High normal values for total and free acid.

X-ray examination: Pituitary fossa normal in size, contained a few small flecks of calcium. Slight ventricular enlargement with some widening of aorta. Only osteoarthritic changes in lower spine and pelvis.

Progress.—Headache soon ceased but ptosis remained in spite of treatment with thiamine. In order to allow patient to see, one lid was strapped open during the day but after a week an ulcer appeared. The opposite upper lid was strapped open with similar result. Apart from constipation he had no abdominal symptoms, and general condition improved slightly. Jaundice difficult to detect. Serum tests on 2.12.47: Van den Bergh direct positive in three minutes, indirect 0.8 mg.%. Total protein 5.47, albumin 2.70, globulin 2.77 grammes%. A/G ratio 1/1. Alkaline phosphatase 32 units, gold test +5. Thymol turbidity 20 units. Thymol flocculation 4+.

POSTSCRIPT (6.2.48).—During the last two months there has been a very gradual improvement, the left eye is now a third open and the right a quarter.

in a paper read before the American Dermatological Association, but not yet published, stated that tocopherols are beneficial in certain dermatoses in which collagen metabolism seems to be disturbed.

Dr. H. W. Barber: I have had a good many cases of this kind. The first point is whether one agrees with Ormsby in considering lichen sclerosis as being distinct from atrophic lichen planus. I feel that, clinically and histologically, the conditions are distinct. The majority of cases in which I have diagnosed lichen sclerosis have been women after the menopause, and usually it has affected what I call the menopausal areas—the vulva, the neighbouring parts of the groin and buttocks, and the submammary and axillary regions. I have treated some by oestrogens given by mouth, but two or three cases by local applications of either 2·5 of 5% dienoestrol cream. It is of interest that vitamin E has been advocated for disturbances of the menopause.

Dr. R. M. B. MacKenna: With regard to the vitamin E question, I am using vitamin E entirely experimentally and am very conscious that I have not got the preparation of vitamin E that I require. I have in two cases seen women with lichen sclerosis associated with pruritus vulvæ, as described by Dr. Elizabeth Hunt. In these cases 3 mg. of α -tocopherol four times a day were given, and in that non-significant number of cases the women have returned after a short period and have said that the pruritus had completely disappeared. The possible action of the drug is a complicated matter: probably it is associated in some way with endocrine biochemistry and requires yet some considerable research. J. F. Burgess of Canada, who has done much original work on the use of tocopherol in disorders of the skin, says that chronic lupus erythematosus, granuloma annulare and possibly scleroderma and lichen sclerosis may be beneficially influenced by large injections of mixed tocopherol—100 to 300 mg. every day. We cannot get this synthetic preparation over here, and α -tocopherol, which we can obtain, is not very suitable for injection intramuscularly, because such bulky doses have to be given that the buttocks are made very sore.

Case for Diagnosis. ? Poikiloderma of Civatte.—R. T. BRAIN, M.D.

Mrs. B. L., aged 38, was seen for the first time to-day and gave a history that she first noticed a pigmented area on the left cheek about three years ago. The colour varied a little from time to time but the area extended and before long the pigmentation affected the other cheek. Her periods began at 13 and have been regular, lasting three to five days with some pain on the first day. No skin reactions to menstruation have been noted. She has two sons, aged 12 and 16. The only medicine she takes is senna, but she has constantly used a cosmetic cream on her face.

On examination.—The patient is in good general health and is blonde with a pink complexion. The abnormal feature is a patchy brown or brownish-red macular pigmentation affecting her cheeks, particularly at the sides of her face, extending slightly to the neck. Many fine telangiectases are seen amongst the pigmented macules which produce a coarsely mottled pattern with a finer reticulated character in some parts. It is thought that a few minute areas of atrophy are present in the pigmented areas but the degree of atrophy is slight. About the temples, especially on the right side, the follicular openings are unduly patent but do not show the coarse plugging suggestive of lupus erythematosus.

Although this patient presents many of the features attributed to the variety of poikiloderma described by Civatte it is believed that these features are not essentially different from those described in some cases of Riehl's melanosis which have been ascribed to contact with mineral oils and tar. This patient has used the same face cream constantly and the opinion of members is sought as to the possibility of her pigmentary dermatosis being the result of the constant application of this oily product which contains some paraffin and various aromatic oils, including oil of bergamot. Somewhat similar cases seen in the last few years have appeared to be more dependent upon contact with greasy preparations than to be related to some endocrine disturbance, as was originally suggested by Civatte, and one has had little success with the treatment of such cases by hormone therapy, although Dr. Barber and others have reported successful treatment with oestrogenic hormones in characteristic cases of Civatte's syndrome.

Comment.—A case was recorded by Dr. MacLeod (*Brit. J. Derm.*, 1931, 43, 420) of acquired epidermolysis bullosa affecting the hands only in a man aged 50. The condition was then of four years' duration. He had a remission in the winter of 1930 lasting until May 1931, during which time he had been able to use his hands freely—sailing, gardening, &c. There was no apparent explanation either of the remission or relapse.

I have recently had under observation for a long time a similar case—a man aged 67—who also had ichthyosis, which had become more severe of late. Some of the earliest bullous lesions occurred in the larynx and Mr. Scott-Brown suggested the diagnosis of pemphigus, with which I at first concurred. The buccal mucous membrane was severely involved, and eventually the clinical picture became very similar to that of the present case. Investigations and various treatments proved of no avail.

Dr. J. T. Ingram; I have had two cases of this type. One was a woman who was aged 44 when the condition started, and it continued for about twelve or thirteen years when she appeared to recover. It was mostly on the hands, with more damage to the nails than in Dr. Barber's case, and some epidermic cysts were present. The other patient was a man whom I had under my care for several months in hospital, and he had been affected for ten years. He was then 44 or 45 years old, and he had not worked for eight years. He also had severe mucosal lesions and developed spontaneous bullæ. He died eventually from bronchopneumonia. I have been very interested to see Dr. Barber's case.

Lichen Sclerosus et Atrophicus treated with Vitamin E.—R. M. B. MACKENNA, M.D., and BRIAN F. RUSSELL, M.D.

Mrs. J. A., aged 58.

November 1946: She noticed a white spot in the right groin and later in the left, which she attributed to an emotional disturbance.

April 1947: The condition spread to the axillæ.

May 1947: It spread beneath the breasts with severe itching.

June 4, 1947: The condition became worse following a bereavement.

She also complains of sharp pains in the groins and much mental depression, with excessive sweating at the time of onset but not since the condition has developed. Her last menstrual period was at the age of 43.

On examination (April 1947).—White, atrophic and patchily pigmented, slightly infiltrated plaques on the anterior and inner aspects of the thighs, also on the right buttock and in the axillæ, less marked under the breasts. Mucosæ normal.

Treatment.—She received treatment with diœstrol, phenobarbitone, and unguentum alcoholium lanæ, without apparent improvement. Since August 6 she has been treated with vitamin E (α -tocopherol) one 3 mg. capsule three times a day.

The lesions now appear much more supple, particularly the axillary and sub-mammary lesions, but biopsies taken from the lesion on the left thigh on April 18 and October 1, 1947, show no appreciable dissimilarity. They both show an atrophy of the epidermis with some increase of pigmentation in the basal layers, fibrosis in the upper part of the dermis, and an occasional perivascular collection of chronic inflammatory cells.

POSTSCRIPT.—The patient developed a seborrhœic type of eruption on the trunk, controlled by salicylic acid and sulphur, following her attendance before the Section.

Comment.—Vitamin E (a mixture of α and β -tocopherol) is said to control the production of œstrins if given in excess. Of these, α -tocopherol is thought to be the anti-sterility factor and β -tocopherol is thought to supply myotropic and neurotropic factors. Good results have been claimed in myopathic conditions. Recently Burgess

in a paper read before the American Dermatological Association, but not yet published, stated that tocopherols are beneficial in certain dermatoses in which collagen metabolism seems to be disturbed.

Dr. H. W. Barber: I have had a good many cases of this kind. The first point is whether one agrees with Ormsby in considering lichen sclerosus as being distinct from atrophic lichen planus. I feel that, clinically and histologically, the conditions are distinct. The majority of cases in which I have diagnosed lichen sclerosus have been women after the menopause, and usually it has affected what I call the menopausal areas—the vulva, the neighbouring parts of the groin and buttocks, and the submammary and axillary regions. I have treated some by oestrogens given by mouth, but two or three cases by local applications of either 2.5 of 5% dieneoestrol cream. It is of interest that vitamin E has been advocated for disturbances of the menopause.

Dr. R. M. B. MacKenna: With regard to the vitamin E question, I am using vitamin E entirely experimentally and am very conscious that I have not got the preparation of vitamin E that I require. I have in two cases seen women with lichen sclerosus associated with pruritus vulvæ, as described by Dr. Elizabeth Hunt. In these cases 3 mg. of α -tocopherol four times a day were given, and in that non-significant number of cases the women have returned after a short period and have said that the pruritus had completely disappeared. The abnormal feature is a patchy brown or brownish-red macular pigmentation affecting her cheeks, particularly at the sides of her face, extending slightly to the neck. Many fine telangiectases are seen amongst the pigmented macules which produce a coarsely mottled pattern with a finer reticulated character in some parts. It is thought that a few minute areas of atrophy are present in the pigmented areas but the degree of atrophy is slight. About the temples, especially on the right side, the follicular openings are unduly patent but do not show the coarse plugging suggestive of lupus erythematosus.

Although this patient presents many of the features attributed to the variety of poikiloderma described by Civatte it is believed that these features are not essentially different from those described in some cases of Riehl's melanosis which have been ascribed to contact with mineral oils and tar. This patient has used the same face cream constantly and the opinion of members is sought as to the possibility of her pigmentary dermatosis being the result of the constant application of this oily product which contains some paraffin and various aromatic oils, including oil of bergamot. Somewhat similar cases seen in the last few years have appeared to be more dependent upon contact with greasy preparations than to be related to some endocrine disturbance, as was originally suggested by Civatte, and one has had little success with the treatment of such cases by hormone therapy, although Dr. Barber and others have reported successful treatment with oestrogenic hormones in characteristic cases of Civatte's syndrome.

Dr. A. C. Roxburgh: There were a number of cases in Brazil or Argentina some time ago during the war which were ascribed by the man who wrote the paper to the use of inferior cosmetics. He said that among the passengers on a bus or tramcar one could find several people every time with this pigmented condition of their faces. The South American races no doubt pigment more easily than we do.

The President: I have seen a number of such cases and am still very much of the opinion that the external application of some oily or greasy agent is an important factor. In one case, "patch testing", without exposure to light, produced no erythematous reaction at all, but simple pigmentation.

Dr. H. W. Barber: Apart from the pigmentation, two essential features of Civatte's condition are telangiectasia and slight atrophy. I do not quite understand how cosmetics could produce these two changes.

Dr. Theresa Kindler: I think most of the original cases described were in women. In 1924 Kerl published a survey of 17 cases from the Clinic Riehl of which 2 were men, 2 children, the rest women of various ages, mostly in domestic occupations.

On the question of external or alimentary causation, Riehl and his school thought that the disorder was caused by a toxic agent contained in the war bread. They separated it from Hoffmann's and Habermann's melanodermatitis toxica, which is caused by external irritants such as tars, mineral oils, and kindred substances. Riehl considered the absence of inflammation and the involvement of the scalp to be distinctive symptoms of his disease. Most other workers think that the two conditions are identical or closely related, and that both alimentary and external toxic agents, by producing a sensitization to light, are responsible for the disorder. The poikiloderma Civatte also is usually included in this group.

Dr. W. N. Goldsmith: Pigmentation attributed to petroleum, coal, and tar first aroused interest during World War I, when lubricating oils and other derivatives were used in a crude state, especially in Germany and Austria. Thus, in 1917, Oppenheim described a case of intense, brown-black discoloration of the face and neck from lubricating oil. In the same year Riehl published his cases, which were at first attributed to the ingestion of other food factors, and later possibly to petroleum used as a constituent of margarine.

The President: It is not without interest that at the time Riehl's original papers were published, describing the condition as war melanosis, there was considerable malnutrition amongst the population with whom he was dealing. I think we have seen more cases recently than we saw during the period before the war, and it is a fact that there is not as good nutrition in this country as there was. This may be a factor as well as the oils. In some cases there seems to be no possibility whatever of oil absorption.

Dr. Henry Corsi: I read Riehl's original paper, which was published in 1917. He assumed in it that the condition was due to malnutrition. Later on that idea was abandoned by everybody, including Riehl, and the condition was believed to be due to an external irritant. Riehl's cases were nearly all men, but not exclusively so. The physical signs were a large amount of pigmentation, but scarcely anything else. In the present case there is a change in texture and a poikiloderma, i.e. a variegation in pigment instead of mere increase, which was the main feature of Riehl's cases. It does not seem to me therefore that the present case can be classed as one of Riehl's type of pigmentation; it is more closely allied to the poikiloderma of Civatte.

Dr. W. Lemberger: In addition to pigmentary anomalies there are in quite a number of cases certain hyperkeratotic excrescences on the back of the proximal phalanges. The condition does not consist of pigmentary anomalies alone.

Other cases were shown as follows:

Lichen Planus in Linear Distribution.—Dr. J. D. EVERALL (for Dr. L. FORMAN).

? Lichen Planus.—Dr. C. H. WHITTLE.

Granuloma Annulare with Extensive Lesions.—Dr. R. M. B. MACKENNA.

Darier's Disease.—Dr. D. WEITZMAN (introduced by Dr. J. E. M. WIGLEY).

Total Alopecia treated with Thorium X (Four Cases).—Dr. P. J. FEENY.

(1) **Leucoderma and Leucotrichia.** (2) **Erythema Induratum and Papulonecrotic Tuberculidè.**—Major J. MORGAN, R.A.M.C.

Keratoderma Blennorrhagicum.—Dr. G. B. MITCHELL-HEGGS, Dr. J. J. KEMPTON and Dr. M. FEIWEL.

... to be published later in the *British Journal of Dermatology*.)

[November 20, 1947]

(?) Eczematoid Tuberculide.—H. W. BARBER, F.R.C.P.

Dr. J. S.

History.—An eruption appeared on the left hand September 1946. In November 1946 a radiograph of the chest revealed evidence of tuberculosis of the apex of the left lung and for this he has been under the care of Dr. E. R. Boland. The left hand was treated by X-rays with success. In May of this year he ran a splinter into the right palm and at this point the existing eruption appeared and spread to its present extent. Treatments with lotions and ointments were apparently ineffective. He has been under the care of Dr. Erskine until quite recently, and at the latter's suggestion he consulted me.

Eruption.—The patient is an ichthyotic. There is a vesicular eczematoid dermatitis involving the greater part of the right palm with sharply margined borders. Although it is unilateral, the appearances do not suggest a dermatitis from an external irritant. In view of the history I thought the possibility of an eczematoid tuberculide had to be considered, and a patch test with tuberculin jelly was performed on the left forearm. This provoked an acute vesicular eczema with a few pustules. Control test negative. As with other positive patch tests, the fact that the epidermis is sensitive to the substance applied is, of course, not proof that the substance in question is responsible for the existing eruption but, in the absence of any other apparent cause, it seems to me likely that in this patient the palmar eczema is due to epidermal sensitization to tuberculin; in other words an eczematoid tuberculide.

In 1920, Attwater, Marshall and I (1921) described a series of cases of an eczematoid dermatitis, occurring almost exclusively in children and adolescents as scaly patches of a characteristic fawn or pale brown colour, usually dry, but sometimes oozing—probably as a result of scratching or rubbing—and situated chiefly on the extensor surfaces of the limbs, the trunk, and on the face, particularly on the temples and forehead below the margin of the hair. In about 80% of the cases described Marshall and Attwater were able to demonstrate definite signs of active tuberculosis. I christened the eruption "dermatitis scrofulosa." Dowling and I (1926) described a further series of cases, and we showed that (1) exactly similar patches may arise *de novo*, and persist for some time in tuberculous children at the sites where von Pirquet's test with tuberculin has been done, and (2) in children with dermatitis scrofulosa, patches identical in appearance and histological structure with those already present may be produced by applying tuberculin to the skin. We also observed cases of undoubted lichen scrofulosorum, in which patches of dermatitis scrofulosa were coexistent, and put forward the view that the latter is an eczematoid variety of the former. I am also of the opinion that the so-called "fausse teigne d'Alibert" is in some cases dermatitis scrofulosa occurring on the scalp.

Some years ago a child whom I had treated in infancy for eczema was brought to me for scaly patches on the limbs and trunk, which were characteristic of dermatitis scrofulosa, accompanied by slight generalized enlargement of the lymphatic glands. The practitioner in charge of the case was entirely sceptical of my opinion that the child had active tuberculosis, but a week later there occurred an outbreak of typical lichen scrofulosorum, and the late Dr. J. J. Perkins confirmed the diagnosis of tuberculous adenitis.

Hügel, Eliascheff, and Schaumann (1927) have recorded cases of lichen scrofulosorum in which the normal papular eruption was associated with "brownish red scaly patches of psoriasiform aspect". Schaumann found in microscopical sections infiltration with epithelioid and giant cells around the follicles.

Comparable to dermatitis scrofulosa is, I think, the eczematoid trichophytide described by Jadassohn and Guth, and the eczematoid microsporide of Finnerud (1925). It is generally agreed that they are varieties of the lichenoid trichophytide or microsporide, just as dermatitis scrofulosa may be regarded as a variety of lichen scrofulosorum. I believe that these eczematoid eruptions are due to the sensitization of the epidermal cells to the toxins, tuberculin and trichophytin respectively, and the artificial production of dermatitis scrofulosa by applying tuberculin to the skin is in favour of this view.

Gold Dermatitis, treated with B.A.L. Toxic Manifestations ? Related to Calcium Deprivation.—BERNARD GREEN, M.R.C.S., L.R.C.P., and BRIAN F. RUSSELL, M.D.

T. W., male, aged 57.

First seen (B. G.) on October 29, 1947, showing a polymorphous eruption of urticarial, erythematous and exfoliative lesions all over the trunk, limbs, scalp, face and neck.

History.—He had suffered from rheumatoid arthritis for eighteen months, and at his local hospital had been given a course of myocrisin, one per week (total amount not known). About the seventh injection he noticed some irritation of his skin between the clefts of the fingers, but he did not mention this to his doctor. After the ninth injection he reported the irritation, which by this time had spread to the palms. The injections of gold were immediately stopped, but within a few days he developed a generalized eruption with intense irritation. He was given a course of eight injections of intravenous sodium thiosulphate. This helped the irritation and the eruption to some slight degree. He was then given a course of B.A.L., four injections in the first twenty-four hours, two on the second day, and one on the third day. (Total amount of B.A.L. not known.) After the second injection the "rheumatism" returned, particularly in his shoulders, and remained painful for twenty-four hours, then the right knee became affected, the leg being fixed in a flexed position; this remained so for twenty-four hours, when the left knee became similarly affected. He also had a "cramp" of the left hand and forearm lasting one to two minutes; this occurred about four times at various intervals of time. In addition, he had attacks of excessive sweating every night after the injection of B.A.L. whilst in hospital, and a number of shivering attacks—on one occasion he was unable to feed himself and had to be spoon-fed.

He was considered sufficiently recovered from the gold dermatitis, and was discharged from the local hospital about October 15, 1947.

Two weeks later (October 29) he consulted me (B. G.) as a private patient. He was then suffering from a relapse of the gold dermatitis, with lesions as stated above. It was during the time of my examination he developed a tonic muscular contraction of the flexor muscles of his left forearm and hand, which disappeared within a few minutes following massage, and in addition he had a shivering attack.

I had him admitted to St. Bartholomew's Hospital, and ordered a course of B.A.L. to be commenced immediately. The improvement was dramatic, and within a few days he had considerably improved. Whilst in St. Bartholomew's Hospital he had no shivering attacks and no visible contractions of his muscles, but he complained of pain in the right shoulder lasting about two days. He was discharged on November 12, having sufficiently recovered to warrant out-patient treatment.

A series of blood calcium level estimations have been carried out (see Dr. Brian Russell's comment). Chvostek's sign was found to be positive.

Seen on November 17, 1947, when the patient complained of slight irritation all over the body. Examination revealed some fine scaling of the face, scalp, forearms and legs; erythema of scrotum and generalized pigmentation.

Comment (B. G.).—This case demonstrates the possible toxic effects of B.A.L. and its relation to calcium deprivation of the tissues. The points of interest are the pain in the shoulder and knees—with fixation in position of flexion—the tonic contractions of the flexor muscles of the left hand, the shivering, sweating attacks, and the presence of the Chvostek's sign after the injection of B.A.L.

Comment (Dr. Brian Russell).—The occurrence of cramp-like pains in the limbs and carpal spasms in this patient suggested a state of latent tetany, and this was confirmed by the presence of Chvostek's sign. The absence of alkalosis made it probable that the tetany was of low calcium or magnesium type.

Subsequent studies after a test dose of 2.41 mg. B.A.L. per kg. repeated in one and a half hours resulted in the following observations: a rise was noted in systolic and diastolic blood-pressure to a maximum increase of 19 mm.Hg and 24 mm.Hg respectively two and three-quarter hours after the first injection. Diastolic readings were obtained with difficulty at this time, particularly the second and third of each group of three readings. At the same time difficulty was experienced in the withdrawal of samples of venous blood and of inserting the needle in the vein. These difficulties were thought to be due to vascular spasm, particularly as spasm was also noted with galvanism in attempting a quantitative record of Erb's test. This was preceded by a sharp reduction in muscle sensitivity to galvanism, contrary to the expected changes from tetany but at least evidence of a profound disturbance in kationic equilibrium.

Changes considered significant and maximal half an hour after the injections were noted in the serum calcium level.

Nine volunteers and patients have been injected with doses of B.A.L. between 0.75 and 3.34 mg. per kg., and Chvostek's sign became positive in five of these half an hour after the injection, including the recipient of the smallest dose. Of the remainder, one vomited and had cramp, a second had nausea and cramp, the third had cramp, and the fourth was entirely free from symptoms. This was a patient suffering from an acute and severe gold dermatitis, the only one in the series.

Three controls injected with 5% benzyl benzoate in arachis oil in volumes equivalent to those used for administering 1.31 to 2.89 mg. of B.A.L. per kg. had no symptoms or abnormal signs.

A tenth individual injected with 5.71 mg. of B.A.L. per kg. had a positive Trousseau's sign in addition to a positive Chvostek's sign one hour after the injection, and also complained of cramping pains in the chest, abdomen, shoulders, knees, calves and toes, with stabbing pains in the eyes, tickling, constricting sensations in the throat, and pains in front of the ears.

In addition to changes in the serum calcium level, significant changes in serum inorganic phosphorus (25%) and serum magnesium (65%) have been noted in the only patient so studied up to the present, but the serum potassium and serum sodium have not shown appreciable changes.

Finally it is noted that the symptoms of toxicity from B.A.L. described by Sulzberger *et al.* (1946) and Modell *et al.* (1946) can all be explained as tetany. Further, Durlacher *et al.* (1946) in animal studies describe a metabolic acidosis attributed chiefly to an accumulation of serum lactic acid and resulting in a reduction in the

pH of the blood and in the plasma CO_2 content, so that the tetany cannot be due to alkalosis and can only be produced by disturbances in pericellular kationic equilibrium probably from depletion or unavailability of calcium or magnesium or both.

Section of Surgery

President—Sir MAX PAGE, K.B.E., C.B., D.S.O., M.S.

[November 5, 1947]

Surgical Records

PRESIDENT'S ADDRESS

By Sir MAX PAGE, K.B.E., C.B., D.S.O., M.S., F.R.C.S.

THE title of my Address is perhaps somewhat ambiguous. I may say at once that I do not propose to enlarge upon the high spots of surgical achievement but rather to consider some of the shortcomings of our craft, particularly shortcomings in the keeping of case records and in their application to scientific judgment.

We all seek the truth and endeavour to make wise use of it when it is found; but truth is as elusive in relation to our art as it is in any other branch of science, in particular the barrier to the establishment of satisfactory controls is often insurmountable. Moreover the discipline of science is not natural to man; it seems to come easily to a few but most of us find it a hard taskmaster. New ideas and new methods in surgery are forever coming before us and our task is to use our judgment unworried by impressionism and prejudice.

Looking back on British surgery of the last fifty years one cannot but feel that there was often failure in this respect. These weaknesses are familiar to most of us but I think it may be useful to pass them in review in support of my theme—better records and their more scientific use.

The progress which has been registered in surgery during the past half-century has been so great and has been so generally acclaimed that it seems almost churlish to emphasize the stumblings and backslidings which may be observed in this progression; however, the history of the development of any art is well worth study and may properly furnish later generations with a guide or a warning.

The first half of this century is certainly unique in the history of surgery. From its commencement we were endowed by the pioneer work of Lister, Roentgen and others, with knowledge and methods which, when fully developed, provided a hitherto unexampled precision in diagnosis and safe access to all parts of the body. It is noticeable that early enthusiasm begotten of this new freedom was directed mainly into the field of abdominal surgery and the locomotor system was relatively neglected.

The surgeons of the first decade were naturally influenced by the social atmosphere of their time as well as by the current scientific training. The spirit of Victorian individualism and privilege was manifest in their professional work. Jealousy of colleagues and fear of competition of juniors was too often an impediment to co-operative work. The ambition for personal success, ever a potent incentive to mankind, was often directed to the building up of their private practice, the advancement of surgical knowledge tending to take a secondary place. So far as institutional facilities are considered it may be recalled that in the first quarter of this century London possessed no organized centre for the study of surgery comparable with the Mayo Clinic, the surgical centres of Boston and Baltimore or some of the professorial units on the Continent. Add to this the rigorous and insistent demand that dogs the surgeon for the immediate relief of the sick and it will not appear surprising that with this background scientific judgment of new operations was slow to make itself felt. Of this lag I will now quote some specific examples. Operations for acute appendicitis only came into vogue after Treves had operated on Edward VII in 1902, but once the inflamed appendix was recognized as lawful game for the surgeon, the call for operative treatment at any stage of an attack was soon regarded almost as a law. Indeed it must be remembered that this doctrine was maintained by many surgeons until quite recently. To us it may seem fantastic to break in on an infected intraperitoneal organ which the natural processes have manifestly localized, but the surgeons of thirty years ago were still mechanically minded and gave little credit

to Nature's defence methods. It is true that there were exceptions to this radical attitude: Ochsner, in his book on Appendicitis, published in 1906 made out a strong case for non-operative treatment under certain circumstances. Sperren, who had found in 1905 that the mortality after operations for acute appendicitis at the London Hospital was 19.5%, was inclined to conform with Ochsner's views. However, the lack of convincing records of cases dealt with conservatively as advocated by Ochsner, Sherren and others, and the absence of an analysis of the results of intemperate intervention, were no doubt partly responsible for the persistence of a fixed idea. That we are still not fully informed as to the morbidity and mortality of appendicitis is suggested by some statistics, extracted from the Registrar-General's Report, and put forward by Dr. W. T. Russell at Oxford last summer. They have not yet been published and further work in relation to them is afoot, but here is the main statement:—

THE STANDARDIZED MORTALITY RATIOS FOR APPENDICITIS AT AGES 20 TO 65
FOR MALES DURING THE PERIOD 1930-32 IN ENGLAND AND WALES

Social class	Males			
I	181
II	140
III	98
IV	80
V	76

The standardized mortality ratio is the percentage ratio of the deaths actually registered to the "standard deaths". The "standard deaths" are those which would occur if the population at specific ages in a Social Group died according to the corresponding death-rates for all males in those age-groups.

Why the mortality in the professional and executive classes should be more than double that of manual workers is an interesting conundrum and I will forbear from speculating on it. One hopes that in the near future more light will be thrown on a matter of such close interest to surgeons.

Turning to gastric surgery, the most striking feature was the prolonged popularity of some type of short-circuit operation for pyloric and duodenal ulcer. The want of knowledge of the frequent failures of this procedure when it had been applied to stomachs without obstruction and with a high acid must be attributed to a defective follow-up. The side issues of partial gastrectomy are being brought home to us with a rapidity which is almost disconcerting. No doubt it is possible in this relationship that the evil results may be found to be relatively uncommon when a balanced view is forthcoming after a careful statistical study.

One of the odd vagaries of the surgical generation under review was the craze for various "pexies". This type of operation was first popularized on the kidney; the fashion subsequently extended to the large bowel and the stomach. It may be agreed that fixation of the kidney is justified in certain rare instances of intermittent hydronephrosis; its wholesale adoption as a cure for vague abdominal complaints was, I think, due to a failure to appreciate how often considerable mobility of the organ is present without giving rise to any symptoms. The attempts to fix the hollow viscera, in what was regarded as their proper position, were no doubt due to the reaction of a mechanically minded surgeon to the new evidence brought forward by the novel radiographs of barium shadows. If the position of the bowel so shown did not conform to the current conception of textbook anatomy, then this supposed malposition was held responsible for almost any abdominal complaint. Operative replacement and fixation were felt to be reasonable remedy.

Whatever value these operations may occasionally have possessed for mechanical reasons, and though they did little immediate harm, it is now generally agreed that they fall into the category of irrational surgery. The basic cause of the complaint remained unrecognized and the operation was little better than a surgical nostrum.

The patients who submitted to this type of procedure belong to a group who will ever be treated in accordance with the prevailing fashion in medicine. Nowadays we generally attribute their troubles to psychological causes or to some upset in the endocrine balance. At any rate we withhold the knife as long as possible.

Another peculiar surgical myth was created by that brilliant surgeon, Arbuthnot Lane, to whom surgery owes a full appreciation of the meaning of asepsis. His conception of the role of intestinal stasis in man led him to advocate at first short-circuiting procedures, and, subsequently, extensive colectomy for conditions as far separate as chronic mastitis and toxic goitre. I do not think his practice was widely followed in the profession but this development forms an interesting example of how far a strong and imaginative personality can lead surgical judgment into mythical fields when unfettered by scientific control.

A more definite example of the lack of guidance from proper records is to be observed in the assessment of the value of hernia operations. For thirty years or more after Bassini's method and its various modifications had been widely accepted, almost any surgeon, in his publications or in conversation, would express the opinion that there was hardly any recurrence after his own operations. Yet an independent investigation of some 300 cases undertaken in 1934 by Barrett and myself showed that the recurrence rate for inguinal hernia occurring in the Metropolitan Police was over 20%. I must admit that our figures were not exposed to statistical criticism of the expert class, but similar results have since been published by other observers. It cannot be said that the operative cure of hernia is yet established on an agreed basis, but the figures referred to have drawn attention to some of our failures and have provoked a closer consideration of technique and stimulated the establishment of better follow-up systems.

In connexion with the surgery of the breast there are some outstanding problems which one might think should have been settled ere now on a statistical basis. The views we adopt in this field have most serious repercussions on the well-being of the patient and have excited interest among surgeons for many years. I refer first to the theory that cystic disease in a breast predisposes to the development of carcinoma; clinical experience of many, and some animal experimental work, does not favour this view, but the crucial proof by figures does not seem to be available. Secondly, some surgeons are still in doubt as to the necessity for a full radical amputation in all instances of carcinoma of the breast.

In the field of fracture work satisfactory statistical guidance, both on general principles and in relation to the management of individual fractures, had to wait for the establishment of organized fracture clinics of which Sir Harry Platt was the protagonist in this country. I think that the major problems of delay, or failure in union, are not yet conclusively solved. This may well be attributed to the absence of a true statistical picture of the incidence of these conditions in relation to the various methods of treatment.

So far I have quoted examples from what is called general surgical practice. In the field of the major specialties, genito-urinary, neurosurgical and thoracic, I am ill-placed to be critical, and in general I can but applaud the level of achievement in these groups. I think that there is little doubt that those who specialize have maintained a high standard of case records with emphasis on careful follow-up methods. This statement also applies to most of us in relation to our own major interest—and few of us are not specialists in some measure nowadays. One may deplore the gradual extinction of the general surgeon, but one has to face the fact that the spear-head of surgical advance rests now in the hands of the specialist. The general surgeon will, of necessity, survive in isolated areas and in the Services, but how he is to be replaced in our educational system is a difficult question to answer. We shall always need some authority to synthesize the elements of surgical advance, an authority that can present a broad view of the surgical scene for the benefit of new recruits. Perhaps the mantle will fall on the broad shoulders of the whole-time professors.

Returning to my thesis I think I have shown that in the course of its rapid development modern surgery has been over-dependent on judgments tinctured by the emotional reactions common to mankind, and that it has largely failed to utilize statistical research. No doubt each generation of scientific men tends to

emancipate itself further from its intellectual inheritance and the present one is in need of no incentive in this direction from me. To have all surgeons fully trained as scientists is neither possible nor perhaps desirable, but it certainly behoves us so to plan our work that wherever possible scientific statistical control may be facilitated. I would submit that we should give greater attention to our records and systems of follow-up which must form the basis of any such study.

Case records have a dual purpose, the individual and the general. The purpose of the first is to conserve and provide medical information about the patient in his future interest. To this end the inclusion of accurate information from all departments under one cover, so indexed as to be easily obtainable, is obviously desirable. The second purpose is to provide the material which will facilitate the collation and comparison of varying forms of treatment. They are the bricks without which the statistician cannot build. It is in this latter respect that we are faced with the difficulty of selecting or omitting facts. We are all familiar with the difficulties met with when an investigation is undertaken which involves abstracting notes from several institutions; too often one is baulked by the absence in many records of some crucial information. This is a difficult matter to remedy and one is forced to the conclusion that most organized study requiring statistical information must be planned ahead, an agreed pro forma being circulated among those taking part in the investigation.

It is evident that since the first World War there has been a considerable advance in the keeping of surgical records. Individual surgeons and institutions have led the way. I think the establishment of wholtime surgical units has been a powerful influence assisting this change.

It may be said that surgical judgment must depend mainly on pathological knowledge and clinical judgment, none the less there are certainly many questions that can only be answered by statistical investigation and there is at present a strong movement in favour of a more scientific use of that method.

In the sphere of public health and social medicine the essential need for the work of a statistician is fully recognized. I have not enough knowledge to know how far he can assist the surgeon but I think his help should clear up many problems which have for long baulked us. I trust we shall maintain a critical, but open mind towards any new surgical experiment, and while welcoming help from any source which may assist the advancement of the standard of our art we need not be mesmerized into the acquiescent reception of all records stamped with a statistical hall-mark.

Mr. H. Cotton said that planning for health in all manner of ways was a very topical subject. The essential precedent to successful planning was a full knowledge of the facts, and then not as isolated facts, but in relation to one another. The lack of related knowledge was marked in the field of health and sickness. Mortality statistics, which had been available for over one hundred years, did not reflect the sickness situation, nor did they indicate the range or the success of surgical procedures. His theme for that evening was that surgery did not do itself justice. The true greatness of surgical achievement was concealed, due to the lack of simple records made at the time and on the spot by the only persons able to make them authoritatively. From the aggregation of such reliable records much could be made to emerge. Statistics, whether elementary or recondite, could never be better than the records from which they were compiled. He had to confess that when he examined hospital records he was chiefly impressed by the amount of information which was lacking. There were frequently the most gross omissions in a patient's notes, many of which were so sparse as to be of no real value. While oral instruction and visual demonstration were still the best methods of instruction, there had been such a growth in the range of knowledge that these could not be given to everybody on every subject. Therefore there had to be more reliance on published and unpublished records, whether in the form of books or individual case notes. Where these were defective, seekers after knowledge were deprived of necessary instruction.

But the prime function of the record was that of assisting the surgeon in the treatment of his patient. He would define a medical record as a collection of authenticated observations, opinions, reminders, and instructions. It was a scientific instrument if it presented accurately, in a form comprehensible to others, the facts observed, the procedures undertaken, the reaction to these procedures, the results of tests, the narrative of progress, and the long-term results of all of the work carried out. With such a scientific instrument, wherein the various measurements, assessments, reliefs and results of the patient's illness or injury were rationally arranged, easy to read and capable of summation where large numbers of cases presented broadly similar characteristics, the surgeon had, he suggested, an instrument of no less worth than certain of the weapons in his theatre armoury.

The statistical data provided by the hospitals of this country, and even of America, were singularly lacking in even gross details of information, although some institutions and clinics did furnish particulars of their own work. But such refined statistics were not of the value they could be were they placed against the broad background of gross figures. Nor was there a satisfactory common code of nomenclature of the various surgical practices and procedures.

He thought that the development of surgical recording should proceed in stages. The surgeon's time had to be conserved; all that should be expected of him was that he should say what each record should contain concerning his own work.

Thus there was a necessity for pre-arrangement, as follows :

- (1) Prior agreement on what are operative procedures and what are not.
- (2) Agreement as to which operative procedures are to be recorded and which are not.
- (3) There must be an accepted terminology of operations.
- (4) Agreement on the point in time at which the end-result of a given type of operation is assessed.
- (5) Every convenience must be provided for the surgeon to contribute to the record without interfering with his main job.

In regard to the first it was possible to define an operation if one accepted certain basic groups, as had been suggested by the American Medical Association in their publication entitled "The Standard Nomenclature of Disease and Operations". Fundamental surgical procedures were there divided into nine groups, namely: incision, excision, amputation, introduction, endoscopy, repair, destruction, suture and manipulation.

There was an infinity of variants in operative procedures as well as in complaints, so that, unless some guiding principles were laid down, the data might defy compilation. With regard to operative terminology the ground was particularly difficult, since there was a lack even of nationally accepted nomenclature of operations. This made the work of any lay statistician very difficult indeed. The curse of the non-surgeon in dealing with surgical terminology was the eponym, and a descriptive term should here be added for the benefit of the inexpert.

Another difficult point arose in statistics of the end-results of operation. The day-to-day preoccupation of surgeons did not allow of comprehensive follow-up departments. But if follow-up and final assessments were prescribed for only 12 or 20 of the commonest operations, some basis of comparability could be achieved.

He turned now to what the surgeons were entitled to expect in return for all this. There was a necessity for some type of pro formas and questionnaires in which the physician or surgeon was asked to fill up only that part which could not be filled up by anyone else. The first need was for a standard operation report, not complicated by headings for all sorts of rare occurrences, but covering the simple facts of what was found and what was done. From this there could be compiled an operation census, which must precede any refined statistics. For the surgeon interested in the particular operation there was no difficulty in designing a form of report from which even the most esoteric statistics could be compiled. It was essential that operation

reports should be made immediately the operation was over. It was sufficient if the surgeon barked out a swift summary of his discoveries and his actions to some assistant who had the necessary tablets on which to set them down. There was also the method of using a dictating machine.

The operation record was, of course, no more than a part of the general record of the patient during his stay in hospital; many other contributors furnished material to the complete record, which was an instrument in the hands of a clinician, a synthesis of everybody's findings. It was also an educational, research, planning and administrative instrument.

An outstanding need to-day was for a broadly uniform system of medical record-keeping in British hospitals. His conception of a uniform system did not mean regimentation. But it meant that all hospitals should follow a few well-defined, easily comprehended principles, and that individual hospitals should make such adjustments as they desired. From this it followed that there was a need for persons versed in the plan and skilled in the technique of medical record-keeping.

[December 3, 1947]

DISCUSSION: THE TREATMENT OF CANCER OF THE BREAST. [Abridged]

Sir Gordon Gordon-Taylor, after outlining the age-long history of cancer of the breast, continued: Time is lacking to recount the whole story of the evolution of what till a few years ago might have been veritably termed radical mastectomy performed in the "proper cancer spirit", and I would refer those interested to the learned papers of William A. Cooper of New York and our own lamented Sir D'Arcy Power. The descriptions of many of these pristine operations are reminiscent of the martyrdom of the saints, while the barbarous armamentarium of men like Scultetus, Fabricius Hildanus, Bidloo or Tabor to facilitate the removal of a breast recalls the crude methods and cutlery of *les sales Boches* within more recent times.

The spirit of chauvinism still burns within me, and I gladly pay my humble tribute to those from the Middlesex Hospital who have contributed to the evolution of the radical operation, especially Charles Moore, whose epoch-making paper appeared in 1867, my old surgical teacher Sir Alfred Pearce Gould, whose private assistant I was for nearly ten years, and my distinguished colleague and firm friend, W. Sampson Handley. In 1903, as a fellow-worker in our Cancer Research Laboratories at "Middlesex", I saw the inception of the pathological work which has made Handley world-famous, and the operation which he designed in those far-off days to meet pathological requirements has been that on which I have largely modelled my own surgery of mammary cancer.

I may not have followed Handley in his employment of radium at the time of operation or in the use of post-operative radiation, but have always allowed my own enthusiasm the fullest scope and have more than a dozen times deliberately removed the chain of anterior mediastinal glands along with the internal mammary vessels after resection of the second and third costal cartilages. Now, in retrospect, I rather regret that I have not availed myself of this added step towards the truly radical on many more occasions: my end-results might have been bettered thereby.

Other important contributions germane to this discussion have emanated in more recent times from my own hospital and are deserving of attention: those of Patey, Scarff and R. S. Handley on the histological grading of mammary tumours and its prognostic importance; Brian Truscott's recent and most valuable paper on a "follow-up" of 1,211 cases of mammary carcinoma treated *omni modo* in "Middlesex" from 1926 to 1940; and Thackray and R. S. Handley—distinguished son of a famous father—who have investigated the anterior mediastinal glands in a series of cases of breast cancer.

The varying fashion in the treatment of cancer of the breast might be termed "the wax and wane" of radical mastectomy. For be assured, when once the ancillary methods of surgery are added to the knife in dealing with cancer the extent of the operative removal irresistibly, inevitably becomes curtailed: nor is it otherwise in the treatment of mammary malignant disease. Confidence in pre-operative and post-operative irradiation has for some years indubitably tended to restrict the extent of surgical ablation; curtailment of operation is noted especially in the amount of skin and muscle removed and the clearance of the axilla. By some radium has even been regarded as the equal, if not the superior, of radical surgical removal.

In order to secure some information as to the practice of other surgeons in respect of supplementary radiation, in 1938 I approached 72 of my surgical friends throughout the length and breadth of Great Britain. Four different usages apparently prevailed a decade ago; of the surgeons interrogated 25% made no use of irradiation as a supplement to radical operation; 44% employed some form of irradiation as a supplement to every radical operation; 29% used it only after radical operation in Stage II cases; 2% favoured irradiation with or without a local operation.

How has the employment of ancillary radiation fared since 1938? The distraction of surgical attention towards other problems, especially trauma, during the war years and the absence abroad of many operators of first rank necessarily thrust much of the treatment of cancer on to hard-pressed but ever-willing radiotherapeutic clinics, perhaps especially in those parts of the country which were fortunately spared the ravages and disorderings of war. Unfortunately recommendations are nowadays finding their way into the literature which, so far as the incompleteness of radical mastectomy is concerned, take us back to the procedures of Scultetus and others of the Dark and Middle Ages.

I am not, and have never been a "cancer specialist"; I have never had a cancer clinic or sat among the mighty in Cancer Campaigns. I am a simple soul, a simple surgeon profoundly ignorant of the recondite mysteries of radiation therapy, and very fearful of the wondrous apparatus under the management of these scientific experts. But I would hasten to disabuse you of any thought that I harbour even the very faintest suspicion of antagonism towards my radiotherapeutic confrères, least of all towards my friend and colleague Brian Windeyer, who has so often brought aid to myself and healing and comfort to my patients. I yield to none in my admiration for those who practise the radiotherapeutic art, realizing full well the constant demands on their sympathy and cheerfulness, full of wondering amazement at their devotion in a type of work which may well undermine their own health and may often nigh break their spirit. In respect of the advanced inoperable cases my debt to these men is incalculable, and it is for this advanced class of case or for patients deemed unsuitable for radical surgery on other grounds than the stage of the malady that I reserve X-ray therapy. Save for one very brief and perhaps fortuitously unhappy period long ago I have personally eschewed the method of post-operative radiation as a supplement to radical surgery in the cases of mammary carcinoma which are by common usage now classified as Stage I and Stage II. For such I have preferred a sharp knife, a stout heart and unquenchable optimism, and have regarded the widest radical surgery untrammelled by ancillary radiation as the method of election in almost every case belonging to these two categories.

Few of the papers dealing with radiation have made any reference to the *morbidity from radiation therapy*: apart from unhappy local effects, the sickness, misery and other untoward sequelæ may lower the patient's resistance to any malignant cells that may remain after surgical operation.

Cancer resistance or immunity.—It is amazing how the disease may return many years after operation, at a time when the original malady has been almost forgotten. Truscott in 1947 from his investigation reiterates the statement of Mitchell Banks in 1900 that no matter how early the case or thorough the treatment, no patient is free from the possibility of recurrence until death occurs from some other cause.

Recurrence has certainly taken place as long as thirty-two years after the initial operation; Frank Steward recorded a thirty-one-year recurrence in a woman operated on originally by Butlin; Bryant relates recurrences at thirty-two, thirty-one and twenty-five years. Verneuil operated on a recurrence thirty years after the first operation; Bowlby on a case dealt with by Sir Thomas Smith twenty-four years previously.

I have myself seen a carcinoma of the breast recur in the pelvis as a mass, the histological structure of which was reported as a "spheroidal-cell carcinoma of mammary type": the breast had been radically removed by Sir Cuthbert Wallace thirty years before. Three cases of recurrence in the scar of a radical mastectomy were observed by me twenty-one, twenty-two and twenty-three years after operations by other surgeons.

In some cases no causal factor except perhaps *age* can be impugned as bearing any relationship to the recrudescence of the malady, but in others recurrence does appear to have been *preceded by intercurrent disease, or by surgical operation for some independent condition*. In one patient of my own a recurrence in the scar developed seventeen years after a radical mastectomy, and a few weeks after a very severe attack of acute pyelonephritis. I have also observed recurrence in the scar following an operation for hæmorrhoids performed sixteen years after the initial amputation. In three cases recurrence followed shortly after a gall-stone operation, and in another patient recurrence seemed to be related to a herniorrhaphy performed under local anæsthesia! In such cases what Sir Alfred Pearce Gould in his Bradshaw Lecture termed "cancer immunity" appears to have been broken down by happenings unconnected with the original disease.

The vagaries and variations of this cancer immunity or resistance are to be occasionally seen in the recurring alternation of efflorescence and retrogression or disappearance of cutaneous nodules and even of lymphatic glands. Preternaturally slow growth of a mammary tumour and the prolonged absence of metastases may be indicative of the same cancer resistance; the most remarkable example is that of Crivelli and Tinca, whose patient had a carcinoma of the breast for forty-seven years, and only in the last two years of her life did the disease obtain the mastery.

Still more amazing are the cases of *spontaneous disappearance of a cancerous mammary growth and its secondaries*. Sir Alfred Pearce Gould in his Bradshaw Lecture quoted a number of his own cases in which this phenomenon occurred, even when the patient had been almost *in articulo mortis*. Not a few of the cases mentioned by my old "chief" were personally known to myself, but I doubt not that many of the older surgeons here have been privileged to see such miracles. "Cancer, even when advanced in degree and of long duration, may get better, and does sometimes get well. Nature unaided may sometimes effect a cure." These statements are based on fact: I have not the wit or wisdom to weave them into theories, but I remain fearful of any form of treatment or contingency which may even temporarily undermine the patient's resisting power to deal with residual malignant cells that may have been left behind at operation. Some of my patients with an axilla packed with infected glands, in whom it seems impossible that every cancer cell can have been removed, have remained well for periods of fifteen to twenty years, in the absence of post-operative X-ray therapy.

Forty years have passed since I performed my first radical mastectomy, and although I have been attached synchronously to a plethora of hospitals, I confess to my surprise in June 1938 to find that I had performed 603 radical operations for carcinoma mammæ. The year that intervened between the Plymouth meeting of the British Medical Association in 1938 and the outbreak of hostilities added another 25, but the war years where my function was that of a consultant rather than an operating surgeon and those of more recent wanderings have only yielded an additional 17 radical ablations. My operative experience therefore amounts to 645 radical operations for mammary cancer, while less than one hundred patients have for various reasons been treated by radiation only, a very few by limited operation

and radiation or left without any active therapy. The ten-year figures which follow¹ are the story of one surgeon's experience, which on the whole has dealt with what might be regarded as a relatively favourable class of case.

Total personal cases of primary carcinoma of the breast, from December 1907 to December 1947 treated by radical operation, radiation alone, removal of the breast and superadded irradiation or no therapy: under 750.

Total cases of primary cancer of the breast dealt with by radical operation from December 1907 to December 1947	645
Total cases of primary carcinoma of breast submitted to radical mastectomy up to June 1938	603
Cases of radical mastectomy from June 1938 to September 3, 1939	25
Cases from September 1939 to December 1947	17
Total	645

Lazarus-Barlow and Campiche, in a statistical survey of 1,976 cases of mammary cancer from the Middlesex Hospital records up to 1904, estimated that the average *natural duration of the untreated disease* was 25.4 months in cases with a large amount of fibrous tissue and few cells, and five and a half years in the more cellular growths. *The average natural duration* of all cases was computed to be three and a half years—a figure with which Rowntree is in agreement. It would therefore be almost impertinent in this assembly of surgeons to discuss five-year results, and I will therefore confine my statistics to ten-year survival cases. It is refreshing to find Truscott in his recent paper considering the fate of patients ten years after treatment.

Total cases of radical mastectomy up to 1928, i.e. cases that could have survived ten years or more	363
Stage I: Cases operated up to 1928	113
Cases surviving ten years	95
Percentage surviving ten years	84.07
Stage II: Cases of radical mastectomy up to 1928	204
Cases surviving ten years	60
Percentage surviving ten years	29.4
Stage III: Cases operated up to 1928	46
Cases surviving ten years	3
Percentage surviving ten years	6.5

By August 1939, 169 (43%) of all my 388 patients in whom radical mastectomy had been performed up to 1929 had survived ten years, many being of course still alive at that time.

Survival between twenty-five and thirty years	8
Survival of twenty to twenty-five years	6
Survival of fifteen to twenty years	33
Survival of ten to fifteen years	122
Total	169

Where information is lacking as to the histological grading of the breast tumour, no two series of cases or of treatments can be fairly compared.—Far be it from me to vaunt the results of my own obstinate old-fashioned surgery or challenge my findings against those of other men and of other methods; almost without exception the conclusions of the surgeon-radiotherapist “combines” are based on a five-year survival basis, which is not a very ambitious yardstick, when the length of the natural history of mammary cancer is borne in mind. When their figures at ten years convincingly surpass those which I have given from radical surgery alone, I may be prepared to solicit the routine aid of radiotherapy for the Stage I and Stage II patients.

¹I have with some reluctance yielded to the suggestion that reference should be made to my own results at five years. The only real difference between the five and ten-year figures concerns the Stage II cases, of whom 40% are alive at five years, and 30% at ten years.

Among cases that have survived more than thirty years one of my patients with several infected glands in the axilla at the time of operation is alive thirty-seven years after; another was run over and killed in a Gloucestershire street accident thirty-six years after operation; a third died thirty-six years after the initial operation from what may have been an abdominal recurrence thirty-six years after; while a fourth is alive and well just over thirty-three years after removal of a carcinomatous breast.

Considerations of time preclude me from dealing with the details of operative technique, or to pay adequate tribute to George Grey Turner in respect of this as in every branch of surgery. There are no minutes left to consider the problem of pain, the œdematous arm, the occasionally dramatic effects of stilbœstrol, the value of sterilization by radiotherapy or the baleful results of pregnancy during the development of the tumour and the relation of any subsequent cysts to recurrence, &c. The patient with enlarged supraclavicular glands will live longer if treated by radiation therapy than by any operative attack. The most profound anatomist and skilful surgeon cannot perform a "block-dissection" of the supraclavicular fossa.

Dr. R. McWhirter: The method of treatment of breast carcinoma now in use in the Royal Infirmary in Edinburgh has been developed in an attempt to overcome the causes of failure of the radical operation. Unfortunately the extent of failure of the radical operation is too often concealed by presenting only the results obtained in highly selected cases. By selecting cases for the radical operation very carefully and by publishing the results only in the cases so selected the survival rates may be made to appear so good that the impression may be conveyed that there is little necessity to consider new and better methods of treatment.

It cannot be too strongly emphasized in the assessment of the value of a method of treatment that the value must be judged not simply on the results obtained when the method is applied but also by the number of cases to which it will apply. If a method can be applied to only a few selected cases it cannot be considered good just because the five-year survival rate is high in the few cases so treated. Cases considered to be beyond a method of treatment are just as much failures of that method as cases actually treated and failing to be cured.

When radical surgery is the only method of treatment available and when all cases coming (whether admitted or not) to a large general hospital are considered I do not believe the five-year survival rate will be found to be higher than 20% to 25%. Haagensen and Stout have shown that of all the cases of breast carcinoma coming to the Presbyterian Hospital in New York only 22.2% are alive at the end of five years. Similar figures are difficult to obtain in this country but Truscott (1947) has shown that of all operable cases (unfortunately he does not include inoperable cases) coming to the Middlesex Hospital in the period 1926 to 1935 only 28% are alive at the end of five years. These figures explain why the Registrar-General is able each year to record an increasing number of deaths from breast cancer. They also provide a better indication of the extent by which the radical operation fails.

FIG. 1.—The number of breast-cancer deaths occurring in patients referred to the Royal Infirmary from the south-east of Scotland has been expressed as a percentage of the deaths recorded by the Registrar-General from the same area.

I believe the number of survivors should be expressed ideally as a percentage of the total cases occurring in the area served by the treatment centre. In Edinburgh we are approaching this ideal, because general practitioners in the area have been specially requested to send all cases, no matter how advanced, and fig. 1 shows that the number of deaths occurring amongst such patients referred to the Infirmary from the south-east of Scotland is approaching the number recorded by the Registrar-General in the south-east of Scotland. In 1946, 85% of the deaths recorded by the Registrar-General occurred in patients referred to the Royal Infirmary.

It will be noted that the two curves are rapidly converging and there is good reason to believe that almost all the cases of breast carcinoma occurring in the south-east of Scotland are now being referred to the Royal Infirmary. The results which will be presented from the treatment method in use in recent years are therefore based on figures showing a lesser degree of selection than any hitherto published. I am not aware of a similar position having been reached by any other centre, and it should be noted that this position was reached in Edinburgh only by requesting that all advanced cases

should be referred. When comparison is being made with the results obtained in other centres it must be appreciated that the survival rates in other centres will be based on a more selected group of cases.

Number of cases.—Since 1930 approximately 3,500 cases have been referred to the Royal Infirmary. For the purposes of this paper only cases from 1930 till 1945 will be included. During this period there were 2,809 cases and of this number 299 were referred only after failure of treatment elsewhere. When these recurrent cases are omitted there are 2,510 cases available for analysis.

TABLE I.—ALL PREVIOUSLY UNTREATED CASES—MANCHESTER CLASSIFICATION

		Stage I	Stage II	Stage III	Stage IV	Total
1930-34	..	138 35%	86 22%	133 34%	35 9%	392 100%
1935-40	..	267 34%	137 18%	157 20%	223 28%	784 100%
1941-45	..	405 30%	344 26%	182 14%	403 30%	1,334 100%
Total		810 32%	567 23%	472 19%	661 26%	2,510 100%

It will be noted from Table I that the number of cases in Stage IV is small in the period 1930-34, because advanced cases were not recorded.

In the period 1941-45 the number of advanced cases (Stage IV cases) is higher than in any other period.

Calculation of survival rates.—The method adopted is that advised by Dr. Lewis-Fanning of the Medical Research Council. It is of particular value in the calculation of the survival rate for the period 1941-45. A full account of the method cannot be given here but briefly it may be stated that, while the five-year survival rate of the cases treated in the period 1941-45 is mainly determined by the cases treated in 1941 the rate is also influenced by the cases treated in the later years. By allowing the more recently treated cases to influence the five-year survival rate a figure is obtained which is more reliable than that based on the 1941 cases alone.

Operability.—The cases have been divided into two groups "operable" and "inoperable". A low standard of "operability" has been accepted because in the earlier years many moderately advanced cases were actually treated by radical excision. It will be appreciated that if a higher standard had been accepted this would have resulted in higher survival rates amongst the "operable" cases. The following standard has been accepted and corresponds to Stages I, II and III of the clinical classification used in Manchester.

The primary tumour, which may be of any size, may show any degree of skin involvement up to and including ulceration but there must be no isolated skin nodules or other manifestation of invasion of the cutaneous lymphatics. The tumour may be fixed to the pectoral muscle but must not be fixed to the ribs. The axillary glands of the same side may be enlarged but they must not be fixed. The supraclavicular glands must not be enlarged and there must be no clinical or radiographic evidence of more distant metastases.

For reasons which will emerge later I believe it is inadvisable in such a definition to take into account the age or general health of the patient.

Untraced Cases.—The percentage untraced over the whole period is 0.24%. In the period 1941-45 only one case is untraced giving a percentage of 0.07%.

Histological examination.—Histological reports are available in almost every case where an operation was carried out and in the period 1941-45 97% of all "operable" cases are histologically proven, and of all the cases in this period 87% are histologically proven.

Methods of treatment used.—From 1930-34 the main method of treatment practised in Edinburgh was radical surgery alone and the cases in this period have been used as a control in the evaluation of other methods. From 1935-40 the main method of treatment was radical surgery followed by post-operative radiotherapy. From 1941-45 the main method of treatment was simple mastectomy followed by X-ray therapy.

The reasons leading to the changes which have been made will now be given.

RADICAL SURGERY ALONE: "OPERABLE" CASES

The causes of failure are so obvious when the radical surgical operation is attempted in "inoperable" cases that such a study is not profitable. But in the "operable" cases careful follow-up yields much valuable information and shows clearly that the operation often fails because of failure to eradicate all the disease in the operation area.

Of 364 "operable" cases treated by radical operation it was found that the number of cases developing recurrences in the chest wall, axilla and supraclavicular region of the side affected was almost 40% within five years of the time of the operation. Admittedly cells may have been present in distant sites as well but the finding showed that in 40% of cases the operation was doomed to failure because the disease was not eradicated locally.

TABLE II.—THE LOCAL RECURRENCE RATE IN 364 "OPERABLE" CASES TREATED BY RADICAL SURGERY ALONE

Years after treatment	Number of local recurrences	Number exposed to risk	Chance of developing local recurrence in any one year	Number developing local recurrences Total = 100
1	69	341.5	.202	20.2
2	20	232.5	.086	6.9
3	16	183.5	.087	6.4
4	8	148	.054	3.6
5	3	119	.025	1.6

The above figures are in general agreement with those published from other centres.

RADICAL SURGERY WITH POST-OPERATIVE RADIOTHERAPY—"OPERABLE" CASES

From this finding the first step was obvious and in 1935 it was decided to try the effect of post-operative radiotherapy to see if this procedure would be effective in destroying cells in the area of operation. The following table shows that it was effective and that the number of local recurrences has been reduced from 40% to 14%.

TABLE III.—THE LOCAL RECURRENCE RATE IN 278 "OPERABLE" CASES TREATED BY RADICAL SURGERY AND POST-OPERATIVE RADIOTHERAPY

Years after treatment	Number of local recurrences	Number exposed to risk	Chance of developing local recurrence in any one year	Number developing local recurrences Total = 100
1	9	271	.033	3.3
2	13	220.5	.059	5.7
3	5	171.5	.029	2.7
4	2	129.5	.015	1.4
5	1	86	.012	1.0

As might be anticipated from the foregoing remarks the five-year survival rate was higher and it was found to be raised from 37% for radical surgery alone to 51% when radical surgery was followed by post-operative radiotherapy. These figures still leave much to be desired for it must be borne in mind that the survival rates presented refer only to cases actually treated and take no account of the many cases treated only palliatively or not treated at all. It is important to do everything possible to raise the five-year survival rate in breast carcinoma because of all types of malignant disease in women, the breast is the site affected in 25% of cases. The disease, too, often occurs in young patients and one in eleven of the patients in this series was under 40 years of age.

SIMPLE MASTECTOMY WITH POST-OPERATIVE RADIOTHERAPY

It must be noted that however successful the localized post-operative radiotherapy may be the patient will still not be cured if cells have escaped beyond the area treated by X-rays. Some cells may have escaped to distant sites before the operation was performed but the possibility must now be considered of cells escaping beyond the operation area either at the time of operation or before X-ray treatment could be applied.

Because the radical operation not uncommonly fails to get rid of all the tumour tissue in the operation area it follows that at the time of operation tissues actually invaded by tumour must often be divided. The trauma inflicted on those involved tissues must increase the natural tendency of malignant cells to disseminate to other sites. Should cells be disseminated to other sites before radiotherapy is applied the radiotherapy will not be effective in saving the life of the patient. In an attempt to overcome this difficulty it was decided to explore treatment by simple mastectomy followed by post-operative radiotherapy.

At the time of the simple mastectomy, cells may still be liberated from the operation area on the chest wall but it is unlikely that these cells will escape beyond the intact barrier of the axilla.

Healing of the wound takes place more quickly after simple mastectomy than after a radical operation. Radiotherapy can therefore be applied with less delay. The interval during which cells may escape to distant sites is thus reduced.

The results already published by Keynes further supported the adoption of this method. It will be recalled that Keynes advised radium implantation following the local removal of the primary tumour or simple mastectomy if the tumour was large. He strongly advised against dissection of the axilla. The results obtained were good and the only difference between the present method and that of Keynes is that X-rays are used in place of radium implantation. X-ray treatment was deliberately chosen for no matter how carefully an implant is carried out it is exceedingly difficult to irradiate a large area uniformly and of course, in the areas where the dosage is low, recurrence is likely to take place. With high voltage X-ray therapy this difficulty is largely overcome and a large area may be irradiated in an almost uniform manner.

At first it may seem wrong not to dissect the axilla especially in early cases. In these early cases the axilla may or may not be secondarily involved.

If the axilla is, in fact, not involved it must be admitted that the radical operation is unnecessary, for extension of the operation to the axilla can do no good if there are no malignant cells to be removed.

On the other hand if the axilla is secondarily involved, it will be generally admitted that the results from radical operation are poor. This is the one fact which stands out in every published series of figures, and if one believes that radiotherapy has any part to play in the treatment of breast cancer it is surely desirable to see what results may be obtained from treatment of the axilla by radiotherapy.

Treatment of breast carcinoma by simple mastectomy and X-ray therapy was commenced in 1941 and it soon became obvious that it was possible to apply this method of treatment to almost every case and certainly it could be applied to far more cases than was possible when the radical operation preceded X-ray therapy. In view of what has already been said on the assessment of the value of a method of treatment all cases in each main treatment period will be included in the tables whether the cases were treated by the main method or not, and, in fact, whether they had any treatment or not.

Post-operative deaths have not been excluded from any of the tables. Indeed it has been assumed that the post-operative mortality in those cases operated on outside the Royal Infirmary was the same as within the Infirmary and the deaths assumed to have taken place have been added to the tables.

"Operable" cases will be considered in the first place.

SURVIVAL RATES OF ALL "OPERABLE" CASES

In the period 1930-34 the main method of treatment was radical surgery alone. The number of "operable" cases in this period was 359 and the five-year survival rate is 35.6%.

TABLE IV.—SURVIVAL RATE OF ALL "OPERABLE" CASES IN THE PERIOD 1930-34. MAIN METHOD OF TREATMENT—RADICAL SURGERY ALONE. TOTAL CASES, 359.

Years after treatment	Number of cancer deaths	Number exposed to risk	Chance of dying in any one year	Survival rate
1	89	358	.249	75.1%
2	66	267.5	.247	56.6%
3	32	200.5	.160	47.5%
4	19	166	.114	42.1%
5	22	142	.155	35.6%

In the period 1935-40 there were 569 "operable" cases and the main method of treatment was radical surgery and post-operative radiotherapy. The five-year survival rate is 44%.

TABLE V.—SURVIVAL RATE OF ALL "OPERABLE" CASES IN THE PERIOD 1935-40. MAIN METHOD OF TREATMENT—RADICAL SURGERY AND POST-OPERATIVE RADIO-THERAPY. TOTAL CASES, 569.

Years after treatment	Number of cancer deaths	Number exposed to risk	Chance of dying in any one year	Survival rate
1	94	568.5	.165	83.5%
2	102	472.5	.216	65.5%
3	52	366	.142	56.2%
4	42	307.5	.137	48.5%
5	24	261	.092	44.0%

In the period 1941-45 there were 941 "operable" cases and the main method of treatment was simple mastectomy and post-operative radiotherapy. The five-year survival rate is 55.9%.

TABLE VI.—SURVIVAL RATE OF ALL "OPERABLE" CASES IN THE PERIOD 1941-45. MAIN METHOD OF TREATMENT—SIMPLE MASTECTOMY AND POST-OPERATIVE RADIO-THERAPY. TOTAL CASES, 941.

Years after treatment	Number of cancer deaths	Number exposed to risk	Chance of dying in any one year	Survival rate
1	75	941	.080	92.0%
2	76	668.5	.114	81.6%
3	57	440	.130	71.0%
4	31	230.5	.135	61.5%
5	8	88	.091	55.9%

It will be noted that the five-year survival rate for the period 1941-45 is higher than in the two preceding periods. Statistical examination shows that the differences are significant. The findings therefore suggest that by not dissecting the axilla the risk of dissemination of cells to distant sites is reduced.

This conclusion is supported by the results obtained in the "inoperable" cases.

SURVIVAL RATES IN "INOPERABLE" CASES IN EACH OF THE THREE PERIODS

It was not of course possible or advisable to treat all "inoperable" cases by the method adopted for each period, for many cases were too advanced for any form of treatment or required only palliative treatment. The survival rate in these cases is influenced only by the effect produced by treatment in those cases where the disease is to some extent localized, i.e. in patients with fixed axillary glands, supraclavicular glands or involvement of the cutaneous lymphatics over the breast but with no evidence of more distant spread.

In many of these cases with extensive localized involvement it will be generally agreed that the radical operation is not only an unsuitable method of treatment but, if attempted, will often hasten the death of the patient. Notwithstanding what has been said the presence of supraclavicular glands did not always deter the surgeon from performing a radical operation and occasionally even when the axillary glands were fixed, radical removal was attempted. The term "inoperable" has, however, been retained as it would still appear to be appropriate for all cases in this category.

Simple mastectomy on the other hand may still be applied to cases where the glands in the axilla are fixed and where there are supraclavicular glands present and, as will be shown later, this treatment in association with radiotherapy may be practised with a considerable measure of success. It will be noted therefore that the term "inoperable" is used to denote a case beyond treatment by radical operation but not necessarily beyond other forms of treatment.

Again as this investigation is concerned with the true value of each method of treatment and not merely with the results obtained in treated cases, all "inoperable" cases, however treated, or even not treated, in each of the three main periods will be considered.

In the period 1930-34 few "inoperable" cases were recorded and none survived to the fifth year.

TABLE VII.—SURVIVAL RATE OF ALL "INOPERABLE" CASES IN THE PERIOD 1930-34. MAIN METHOD OF TREATMENT—RADICAL SURGERY ALONE. TOTAL CASES, 33

Years after treatment	Number of cancer deaths	Number exposed to risk	Chance of dying in any one year	Survival rate
1	22	33	.667	33.3%
2	6	10.5	.571	14.3%
3	3	4	.750	3.6%
4	1	1	1.000	0.0%
5	0	0	—	0.0%

In the period 1935-40 the number of "inoperable" cases referred was 221 and at the end of five years only 2.5% were alive. The results are little different from those obtained during the period 1930-34 and suggest that where a radical removal was attempted the post-operative radiotherapy was rendered ineffective by dissemination of cells at the time of operation.

TABLE VIII.—SURVIVAL RATE OF ALL "INOPERABLE" CASES IN THE PERIOD 1935-40. MAIN METHOD OF TREATMENT—RADICAL SURGERY AND POST-OPERATIVE RADIOTHERAPY. TOTAL CASES, 221

Years after treatment	Number of cancer deaths	Number exposed to risk	Chance of dying in any one year	Survival rate
1	138	221	.624	37.6%
2	54	83	.651	13.1%
3	13	29	.448	7.2%
4	9	15.5	.581	3.0%
5	1	6	.167	2.5%

In the period 1941-45 the number of "inoperable" cases was 404 and the five-year survival rate was 14.1%.

TABLE IX.—SURVIVAL RATE OF ALL "INOPERABLE" CASES IN THE PERIOD 1941-45. MAIN METHOD OF TREATMENT—SIMPLE MASTECTOMY AND POST-OPERATIVE RADIOTHERAPY. TOTAL CASES, 404

Years after treatment	Number of cancer deaths	Number exposed to risk	Chance of dying in any one year	Survival rate
1	186	404	.460	54.0%
2	83	182	.456	29.4%
3	25	69.5	.360	18.8%
4	4	26	.154	15.9%
5	1	9	.111	14.1%

Again the survival rates are higher than any obtained before and the differences are statistically significant when comparison is made with either of the two preceding periods.

In 205 (51%) of the "inoperable" cases seen during the period 1941-45 the disease was apparently still localized, whereas in the remaining 199 (49%) there was clear clinical or radiographic evidence of distant metastases. When the localized "inoperable" cases (see page 126) are considered alone, the five-year survival rate is 24.6%, and this figure shows still more clearly the advantages of the method of treatment advocated; as already shown when radical surgery alone, or combined with radiotherapy, were the methods of treatment in use, none or only a few cases survived to five years.

ALL "OPERABLE" AND "INOPERABLE" CASES OF CARCINOMA OF THE BREAST

This analysis would not be complete without consideration of the results of all cases, both "operable" and "inoperable". Unfortunately during the period 1930-34 no records were kept of patients admitted to medical wards, and of patients who were never admitted. Accordingly comparison can only be made between the two periods 1935-40 and 1941-45.

In the period 1935-40 the total number of cases, "operable" and "inoperable", referred to the Royal Infirmary was 790 and the five-year survival rate was 32.4%.

TABLE X.—SURVIVAL RATE OF ALL "OPERABLE" AND "INOPERABLE" CASES IN THE PERIOD 1935-40. MAIN METHOD OF TREATMENT—RADICAL SURGERY AND POST-OPERATIVE RADIOTHERAPY. TOTAL CASES, 790

Years after treatment	Number of cancer deaths	Number exposed to risk	Chance of dying in any one year	Survival rate
1	232	789.5	.294	70.6%
2	156	555.5	.281	50.8%
3	65	395	.165	42.4%
4	51	323	.158	35.7%
5	25	267	.094	32.4%

In the period 1941-45 the total number of cases, "operable" and "inoperable", referred to the Royal Infirmary was 1,345 and the five-year survival rate of 43.1% is higher than that of the period 1935-40. Statistical examination shows that the difference is significant.

TABLE XI.—SURVIVAL RATE OF ALL "OPERABLE" AND "INOPERABLE" CASES REFERRED IN THE PERIOD 1941-45. MAIN METHOD OF TREATMENT—SIMPLE MASTECTOMY AND POST-OPERATIVE RADIOTHERAPY. TOTAL CASES, 1,345

Years after treatment	Number of cancer deaths	Number exposed to risk	Chance of dying in any one year	Survival rate
1	261	1,345	.194	80.6%
2	159	850.5	.187	65.5%
3	82	509.5	.161	55.0%
4	35	256.5	.136	47.5%
5	9	97	.093	43.1%

CARCINOMA BREAST WITHOUT DISTANT METASTASES

When the cases with clinical or radiographic evidence of distant metastases are excluded from the total patients seen in the period 1941-45 the five-year survival rate is 50.1%.

TABLE XII.—SURVIVAL RATE OF ALL "OPERABLE" AND ALL LOCALIZED "INOPERABLE" CASES IN THE PERIOD 1941-45. MAIN METHOD OF TREATMENT—SIMPLE MASTECTOMY AND POST-OPERATIVE RADIOTHERAPY. TOTAL CASES, 1,146

Years after treatment	Number of cancer deaths	Number exposed to risk	Chance of dying in any one year	Survival rate
1	139	1,146	.121	87.9%
2	119	784.5	.152	74.5%
3	75	489.5	.153	63.1%
4	33	249.5	.132	54.8%
5	8	94	.085	50.1%

This finding is all the more remarkable when it is borne in mind that not all those cases were treated by simple mastectomy and radiotherapy. Even amongst the operable cases some were too elderly and others suffering from advanced cardiac disease, pulmonary tuberculosis, advanced rheumatoid arthritis, &c., were quite unsuitable for treatment. It will be recalled too that a number of deaths were actually added to the tables so as to allow for any possible post-operative deaths in cases where the operation was performed outside the Infirmary.

COMPARISON WITH OTHER CENTRES

One of the best-known and most reliable series in the literature is that of Harrington of the Mayo Clinic. His figures probably represent the best results obtainable by surgery in a large number of

cases. Unfortunately the extent of selection is not indicated and it should be noted that only treated cases are included. Some degree of selection may be presumed, for in 40% of the cases microscopic examination of the axillary glands did not show involvement.

The best results from surgery published in this country are those of Gordon-Taylor. His results are far superior to those of any other surgeon in this country and it should be noted that they are the results of an individual surgeon and not those of a hospital.

Truscott's figures are of particular interest because the results are based on a group of cases very comparable to those accepted as "operable" in this paper (*see* Stages I, II and III in his article), and also because they refer to all such cases referred to the Middlesex Hospital in the period 1926-35. It is unfortunate that the results of the treatment methods used since 1935 are not given and it is to be hoped that the publication of these will not be long delayed for such figures indicate the true value of treatment methods far more clearly than the publications of individual surgeons.

The figures of Haagensen and Stout show the five-year survival rate to be expected when radical surgery is the only method of treatment and all cases coming to a large general hospital are included.

TABLE XIII.—COMPARISON OF SURVIVAL RATES

		3-year	5-year	10-year
Harrington (Mayo Clinic)	Treated cases	60.9%	47.6%	31.1%
Gordon-Taylor (Middlesex Hospital)	Treated cases	55.0%	51.9%	43.5%
Truscott (Middlesex Hospital) (1926-35)	All "operable" cases	—	28%	14%
Edinburgh (1941-45)	All "operable" cases	71%	56%	—
Haagensen and Stout (Presbyterian Hospital)	All cases referred	—	22.2%	—
Edinburgh (1941-45)	All cases referred	55%	43%	—

Direct comparison of results is always difficult but the above figures indicate that the method of treatment now in use in Edinburgh has given results which will bear comparison with any other published figures and they give support to the view that the hypothesis underlying the method of treatment is sound.

PRESENT TREATMENT METHODS

The technique of simple mastectomy and post-operative radiotherapy is being continued with the addition of ovarian irradiation which has been added with a view to influencing distant metastases.

TECHNIQUE OF SIMPLE MASTECTOMY AND POST-OPERATIVE RADIO THERAPY

The method of treatment is a combination of two procedures which must be co-ordinated if the best result is to be obtained.

The following points are of importance in the surgical aspect of treatment:

(1) Pre-operative preparation by iodine is contra-indicated because it lowers the skin tolerance to radiotherapy.

(2) The skin incision and the undermining of the skin flaps should be as limited as possible so that tissue spaces outside the area to be irradiated will not be contaminated with malignant cells liberated during the operation.

(3) Excessive skin should not be removed for tension on the skin flaps may be associated with failure of the wound to heal and delay in the application of radiotherapy. Tightly stretched skin flaps do not tolerate radiation well. Skin grafting does not overcome the difficulty, for grafts do not tolerate X-ray treatment well.

(4) Where the primary tumour is mobile on the pectoral fascia, the fascia should not be removed as this promotes fibrosis of the pectoral muscle. If the tumour is firmly fixed to the pectoralis major, the muscle should be removed together with the breast.

(5) If there are no palpable axillary glands no dissection should be performed, but superficial mobile glands in the subpectoral region and outside the axillary fascia may be removed. Any further dissection of the axilla will defeat the whole purpose of the treatment method advocated.

(6) If the patient is very stout it is better to carry out a radical operation because in stout patients it is difficult to deliver an adequate dose of X-rays to the axilla.

(7) Supraclavicular glands should never be removed because these glands are easily and effectively dealt with by radiotherapy.

(8) Adhesive plaster should not be applied to the skin after the operation because this lowers the tolerance of the skin to radiation.

The following points are of importance in post-operative treatment by radiotherapy:

(1) Only one full course of X-ray treatment should be given. The practice of repeated courses at intervals of three to six months has no place in the treatment of any form of malignant disease where

cure is to be attempted and is just as illogical as partial removal of a tumour at intervals of three to six months.

(2) X-ray treatment should be commenced as soon as possible after the operation: the usual interval is two weeks.

(3) The chest wall must be treated by tangential or glancing fields so as to avoid lung fibrosis.

(4) An adequate dosage must be given and in Edinburgh the patients receive a minimal tumour dose of 3,750 r in a period of three weeks.

(5) The X-ray apparatus must be sufficiently powerful to deliver an adequate depth dose in the axilla and it is doubtful if effective radiotherapy can be given with an apparatus of lower voltage than 250 kV.

CONCLUSION

An account has been given of the method of treatment of breast carcinoma now in use in Edinburgh and the results so far as they can be ascertained have been presented. In a few years still more valuable figures will become available.

The results obtained support the view that by not dissecting the axilla the risk of dissemination of cells is reduced, and that radiotherapy is more effective than surgery in the treatment of the axilla. Further evidence of the effectiveness of radiotherapy in the treatment of breast cancer is obtained in the localized (see p. 126) but "inoperable" cases. In those cases there was gross disease present when the X-ray treatment was given and yet at the end of five years 24.6% of the patients were alive. This result is comparable to that obtained by radical surgery alone in all "operable" and "inoperable" cases coming to a large general hospital.

Radiotherapy has been substituted for surgery in the treatment of the axilla and, therefore, a high standard of radiotherapy is essential. Before the method is more widely adopted it is important to appreciate that simple mastectomy and a low standard of radiotherapy will be associated with results poorer than those obtained by the radical operation without any radiotherapy.

Finally it remains for me to acknowledge the co-operation of the surgical staff of the Royal Infirmary without whose support this investigation could never have been carried out.

 TRUSCOTT, B. McN. (1947) Carcinoma of the Breast. An Analysis of the Symptoms, Factors Affecting Prognosis, Results of Treatment and Recurrences in 1,211 Cases Treated at the Middlesex Hospital, *Brit. J. Cancer*, 1, No. 2.

Sir Stanford Cade: To assess the efficacy of treatment it is important to consider the incidence and mortality of the disease. In cancer of the breast the incidence has risen consistently. Between 1935 and 1945 it has increased year by year and in the total period (ten years) 76,430 women died of this disease in England and Wales; the number of deaths in 1945 was 7,291 or over 20% of the total deaths from cancer in women (38,798).

This increase in mortality and in incidence suggests that a review of the present-day methods of treatment is desirable. Such a review should correlate the natural history of the disease with the results of various methods of treatment.

Cancer of the breast as a cause of death is registered in increasing numbers as age advances; the peak is reached in the five-year period 55 to 60 years of age and then declines slowly. I have therefore chosen 55 years as the age at which to consider expectation of life in connexion with cancer of the breast. In comparison with all other sites of cancer (except skin), the breast is the most favourable, that is, the least rapidly lethal site—and this should affect seriously the choice of the method of treatment.

Several authorities, both in this country and in the United States, have computed the expectation of life in untreated cases, of which there is, unfortunately, no lack. The mean duration is 39.3 months, that is, three years and three months. It seems that the "three-year survival", sometimes taken as a measure of success, is less than the natural expectation of life in the untreated case.

To appreciate the achievement or accomplishment of treatment Professor Major Greenwood (1926) investigated the expectation of life of a woman 55 years of age under various conditions. On actuarial estimation the normal expectation of life is 18.87 years; with untreated cancer of the breast it is reduced to 3.8 years. If treatment is given under average conditions, expectation of life is 5.78 years and with treatment under best conditions it is raised to 12.93 years.

What are the best conditions and how do these differ from the average conditions? "Best" or "average" depends on two factors which are interdependent and cannot be separated.

(1) The stage of the disease. (2) The type of treatment.

The best case can be ruined by inadequate or ill-conceived treatment; and conversely, no treatment, however excellent, will make much difference in a bad case. These two factors are, in my opinion, the key to an unbiased assessment of treatment methods.

cases. Unfortunately the extent of selection is not indicated and it should be noted that only treated cases are included. Some degree of selection may be presumed, for in 40% of the cases microscopic examination of the axillary glands did not show involvement.

The best results from surgery published in this country are those of Gordon-Taylor. His results are far superior to those of any other surgeon in this country and it should be noted that they are the results of an individual surgeon and not those of a hospital.

Truscott's figures are of particular interest because the results are based on a group of cases very comparable to those accepted as "operable" in this paper (*see* Stages I, II and III in his article), and also because they refer to all such cases referred to the Middlesex Hospital in the period 1926-35. It is unfortunate that the results of the treatment methods used since 1935 are not given and it is to be hoped that the publication of these will not be long delayed for such figures indicate the true value of treatment methods far more clearly than the publications of individual surgeons.

The figures of Haagensen and Stout show the five-year survival rate to be expected when radical surgery is the only method of treatment and all cases coming to a large general hospital are included.

TABLE XIII.—COMPARISON OF SURVIVAL RATES

		3-year	5-year	10-year
Harrington (Mayo Clinic)	Treated cases	60.9%	47.6%	31.1%
Gordon-Taylor (Middlesex Hospital)	Treated cases	55.0%	51.9%	43.5%
Truscott (Middlesex Hospital) (1926-35)	All "operable" cases	—	28%	14%
Edinburgh (1941-45)	All "operable" cases	71%	56%	—
Haagensen and Stout (Presbyterian Hospital)	All cases referred	—	22.2%	—
Edinburgh (1941-45)	All cases referred	55%	43%	—

Direct comparison of results is always difficult but the above figures indicate that the method of treatment now in use in Edinburgh has given results which will bear comparison with any other published figures and they give support to the view that the hypothesis underlying the method of treatment is sound.

PRESENT TREATMENT METHODS

The technique of simple mastectomy and post-operative radiotherapy is being continued with the addition of ovarian irradiation which has been added with a view to influencing distant metastases.

TECHNIQUE OF SIMPLE MASTECTOMY AND POST-OPERATIVE RADIOTHERAPY

The method of treatment is a combination of two procedures which must be co-ordinated if the best result is to be obtained.

The following points are of importance in the surgical aspect of treatment:

(1) Pre-operative preparation by iodine is contra-indicated because it lowers the skin tolerance to radiotherapy.

(2) The skin incision and the undermining of the skin flaps should be as limited as possible so that tissue spaces outside the area to be irradiated will not be contaminated with malignant cells liberated during the operation.

(3) Excessive skin should not be removed for tension on the skin flaps may be associated with failure of the wound to heal and delay in the application of radiotherapy. Tightly stretched skin flaps do not tolerate radiation well. Skin grafting does not overcome the difficulty, for grafts do not tolerate X-ray treatment well.

(4) Where the primary tumour is mobile on the pectoral fascia, the fascia should not be removed as this promotes fibrosis of the pectoral muscle. If the tumour is firmly fixed to the pectoralis major, the muscle should be removed together with the breast.

(5) If there are no palpable axillary glands no dissection should be performed, but superficial mobile glands in the subpectoral region and outside the axillary fascia may be removed. Any further dissection of the axilla will defeat the whole purpose of the treatment method advocated.

(6) If the patient is very stout it is better to carry out a radical operation because in stout patients it is difficult to deliver an adequate dose of X-rays to the axilla.

(7) Supraclavicular glands should never be removed because these glands are easily and effectively dealt with by radiotherapy.

(8) Adhesive should not be applied to the skin after the operation because this lowers the tolerance of the skin to radiation.

The following points are of importance in post-operative treatment by radiotherapy:

(1) Only one full course of X-ray treatment should be given. The practice of repeated courses at intervals of three to six months has no place in the treatment of any form of malignant disease where

In such cases radiation is the weapon of choice and pre-operative radiation is, on common-sense grounds, from clinical observation of cases and on histological studies, the method of choice. Radium by moulds or plaques, or the more flexible and equally suitable method of X-rays, leads to regression of the disease and transforms a percentage of cases into Stage I cases, suitable for surgery; in other cases the progress of the disease is arrested and life prolonged by many years.

It is necessary to define more precisely what is meant by pre- and post-operative radiation. Pre-operative radiation aims at sterilization of the active neoplasm in the breast, in the skin over the breast and in the axillary glands. Careful histological studies of breasts amputated at various periods after irradiation have been made by many pathologists and show obvious effects familiar in other sites such as the uterus and skin. In contrast post-operative radiation deals, or should deal, with extensions of the disease beyond the anatomical area covered by the radical amputation, namely, the supraclavicular and anterior mediastinal or retrosternal glands and the flaps of skin lifted at the operation. Unless the case is inoperable (in which case it should not be operated), post-operative radiation deals with potential disease—a somewhat speculative treatment. Pre-operative radiation, on the other hand, treats obvious palpable neoplasms. Such treatment is of benefit, not only as a pre-operative procedure, but in a proportion of cases as a sole therapeutic measure, which has been abundantly proved and is, of course, the accepted method in the treatment of recurrences.

There is, in my opinion, an obvious difference in the usefulness of both these methods and a recent statistical analysis by Dr. Stoll of 448 cases of carcinoma of the breast, treated at Westminster Hospital between 1930 and 1942, supports this contention. He found that in Stage I cases post-operative radiation gave a five-year survival of 53%, and pre-operative radiation a five-year survival of 73%. The figures given by E. Berven from the Radiumhemmet, Stockholm, are even more striking: with fixed axillary glands, the five-year survival with post-operative radiation was over 9.7%, whereas with pre- and post-operative treatment it rose to 32%.

Local mastectomy.—The value of local mastectomy is clear cut—it removes the breast and primary tumour. It does not touch the axillary contents and if disease is present there, palpable or non-palpable, operable or inoperable, actual or potential—there the disease remains. As a clinician I am not attracted by the idea of removing part only of a cancer, be it in the breast or elsewhere, if I can, with impunity to the patient, remove all of it, and as the operative mortality of a radical mastectomy is small, and the morbidity limited, I prefer to offer the patient, if otherwise suitable, the bigger and, in my view, the better of the two operations. Simple mastectomy is suitable in the aged, for the removal of a fungating mass, in bad surgical risks with localized disease, in cases where radiation is not available or suitable. Simple mastectomy has its value; it has, like the radical operation, definite limitations. As a routine surgical procedure, regardless of stage of disease or age of patient, it is a retrograde step and is quite unwarrantable.

In conclusion: The choice of the method of treatment should be guided by many factors. The best results following the best form of treatment are not unnaturally achieved in the best cases and so far radical mastectomy achieves this more frequently than all other therapeutic measures.

Radiation is of value:

- (1) As the sole method of treatment in Stage III cases and here the end-results following radiation are better than those following surgery.
- (2) As a pre-operative measure in Stage II cases, where improved results can confidently be expected.
- (3) As a post-operative measure, chiefly in Stage II cases.

With the better education of doctors and patients, more women will report to hospitals at an early stage—it would be a pity if this painfully achieved progress were stultified by a deterioration in our methods of dealing with the disease. If women are to be mutilated by amputation of the breast, let them at least derive the maximum benefit from such mutilation.

Mr. R. S. Handley said that he had removed the second intercostal space gland of the internal mammary lymphatic chain in 20 cases of carcinoma of the breast, and his collaborator, Dr. A. C. Thackray, had examined the material microscopically. The study had so far been chiefly a pathological one with the object of finding out how often the internal mammary glands were invaded in carcinoma of the breast; and the second intercostal space had been chosen because it contained the largest and most constant gland of the chain. In the 20 cases examined, no glandular involvement had been found in 6 patients; both intercostal and axillary glands were invaded in 9; in 3 cases only the axilla was involved and in 2 cases only the intercostal gland. It was easy to open the intercostal space but more difficult to find the gland, though matting of the tissues round the internal mammary artery usually betrayed invasion of the space. The largest invaded gland he had encountered had been the size of an orange pip, the smallest the size of a pin-head. Though clinical recurrence in the second intercostal space was not very common in these days, it was difficult to believe that carcinoma cells lying almost on the pleura were harmless. If the intercostal glands were invaded, the patient could not be cured by surgery alone and additional radiotherapy was necessary. He thought that if the axilla was clinically free from invasion or showed only small mobile glands, the operation should start with a second intercostal space biopsy. If a rapid frozen section showed the space to be free from growth, a radical mastectomy should be done. If, however, the space was invaded, the operation should be limited to a simple mastectomy with additional removal only of such of the axillary contents

Of all factors affecting prognosis, *stage* of the disease is the most important. A distinction should be made between stage and duration, as sometimes a long history is of favourable prognostic significance, as it implies a slow progress and a lower degree of malignancy. Neither site nor size of the tumour, nor age of the patient is of such importance; the physiological state of the breast, pregnancy, lactation or menopause and the histological variety, are significant, but none of these factors—size, site, length of history, histological variety or clinical type—is of such crucial importance as the *stage* of the disease. It is therefore essential to have a clinical classification. Of these, there are many—all suffer from the defect of attempting too much. Some classifications are of theoretical value only. I suggest the following:

Stage I = Tumour of the breast only.

Stage II = Tumour of the breast + skin changes and/or axillary glands.

Stage III = Tumour of the breast + supraclavicular glands or contralateral axillary glands or fixation to pectoral fascia.

Stage IV = Skeletal or visceral metastasis.

Stages I and II are anatomically within the area covered by radical mastectomy; Stage III is beyond surgical excision and Stage IV suitable only for palliative measures by radiation or endocrine therapy.

The zone of demarcation, between good and evil prognosis, between fair or poor chance of survival, is the clinical state of the axillary glands. It is, of course, agreed that sometimes clinically non-palpable glands show histological invasion, and, conversely, palpable enlarged glands show, occasionally, inflammatory changes only—but on the whole the presence or absence of palpable and clinically malignant axillary glands is the best guide to the future of the patient.

It is my contention that in Stage I of the disease the best method of treatment is radical mastectomy. This contention is supported by much evidence and it may suffice amongst the wealth of material to choose a few published results. Thus Truscott (1947), in an analysis of 836 cases at the Middlesex Hospital, found at the end of five years 64% survival in Stage I and only 31% survival in Stage II. A. B. McGraw (1947), in 412 patients, states that of those with axillary nodes involved only 29.6% survived five years, whereas of the patients without involvement of axillary glands 64% survived five years. Table I shows these figures and those of Sir Gordon Gordon-Taylor (1938), Geoffrey Keynes (1939), University College Hospital (1937), the Ministry of Health and my own series up to 1935, reported in 1940.

TABLE I.—EFFECT OF STAGE OF DISEASE ON 5-YEAR SURVIVAL

	Stage I	Stage II		Stage I	Stage II
	%	%		%	%
Truscott	64	31	University College		
McGraw	64	29.6	Hospital	69	30
Gordon-Taylor ..	86	40	Ministry of Health	65	30
Geoffrey Keynes	71	29	Stanford Cade ..	87	29

All these reports show very high five-year survival rates in Stage I cases (Table I).

Post-operative radiation in this group of cases as an additional measure is, in my opinion, of doubtful value. In other words, results do not appear to be improved by adding radiation to the skilfully performed radical mastectomy in this stage, viz. Stage I, that is in the best type of case. This does not mean that I am prepared to deny the patient radiation; and, as a matter of fact, providing radiation is carefully given, there is no reason to deny it to the patient. The mortality of the radical mastectomy is negligible. It was considered important to find out the mortality of radical mastectomy: for this purpose all the teaching hospitals in London and in nine provincial universities were circularized and I am indebted to twenty-two colleagues for the trouble taken to provide the mortality figures. Any death within one month from the operation was considered as an operative mortality. Of 11,014 radical mastectomies 182 patients died, 1.65%. The mortality was higher, 1.9% in the hospital series, where the operations by experienced surgeons and by those under training were pooled together; it was a little lower 1.1% when the mortality in the hands of "master surgeons" only was analysed (3,866 radical mastectomies with 44 deaths). It is emphasized that the risk to life from radical mastectomy is *very low*.

It is now important to draw attention to the limitation of usefulness of this operation. It gives the best results in Stage I. The results in Stage II are much worse and by itself the operation offers a chance of five-year survival in about 20% to 30% of cases only. Stage 2 should be analysed. It comprises the patients with enlarged axillary glands and those with skin invasion. There are three types of skin invasion: (1) The direct spread and fungation—it is the least malignant; (2) the diffuse invasion with oedema—the pigskin or peau d'orange type—it is of grave significance; (3) the invasion of the skin by discrete nodules so admirably described by Sampson Handley—it is a death sentence.

I wish to emphasize the incalculable harm done by radical mastectomy in many cases, with the last two types of skin involvement. The operation in these patients does not prolong life; it seems, in some cases, to open wide every channel for the uncontrolled spread of the disease. Unfortunately, all radiotherapy departments are familiar with cases where within a few weeks or months following operation, the chest wall is covered with numerous metastatic nodules, which break down and cause more suffering than the original disease.

Section of Anæsthetics

President—JOHN CHALLIS

[December 5, 1947]

Posture in Anæsthesia. [Summary]

By J. K. HASLER, M.B.

POSTURE in anæsthesia is a subject about which little has been written except for a few papers which have recently been published in America. During the past few years I have heard of several unfortunate sequelæ as the result of faulty posture on the operating table. Most of these cases were nerve palsies and as little seems to get into print about them I wonder whether they are commoner than is supposed.

In the anæsthetic room.—With adult patients our chief concern should be to see that they are comfortable. Many, however, arrive from the ward with one thin pillow which is often placed under the shoulders, thereby extending the head. When asked if they would like their heads raised they give a deep sigh and say "Yes". Elderly or obese patients dislike lying flat and appreciate an extra pillow. Nor is there any reason why they should be denied one. With younger patients there are two points to observe. First, those who have had adequate premedication arrive in the anæsthetic room asleep. They are often curled up on one side with the head partially muffled in blankets. This is an excellent position in which to induce anæsthesia with nitrous-oxide by means of a facepiece held just above and near to the patient's face. They should not be waked up by being rolled on to the back. The second point concerns small children who come to the anæsthetic room conscious. Many arrive sitting upright on the trolley and it is in this position that anæsthesia should be induced if they show any objection to lying down.

In the theatre.—We now pass to the operating theatre. In 1932 Dutton suggested that for operations on the abdomen a pillow should be placed behind the patient's knees to flex the thighs and relax the abdominal muscles. Then in 1943 Altschule investigated various factors in surgery which interfered with respiration. Among these was the Trendelenburg position which, at an angle of 22.5 degrees, was found to impair respiration by 17%. He says: "The decreases in volume of functional residual and reserve air in the Trendelenburg position are significant in two respects: (a) They indicate that this posture favours atelectasis by collapsing about 20% of the lung, and (b) they indicate that the intrapleural pressure is less negative than normal in the head-down position." In other words this position impairs return of blood to the heart. Prolonged use of this position is therefore unwise in patients with respiratory and circulatory depression including those with shock. Finally in 1946 Case and Stiles investigated the effect that various postures had on vital capacity of respiration. The subjects examined were all conscious and could therefore co-operate to the full. They found that the most unfavourable positions for patients on the operating table are the Trendelenburg, the lithotomy, and those in which bridges or rests are used. Patients operated on in these positions should remain in them for the minimal time commensurate with good surgery. They also suggested that as their subjects were conscious the figures are probably better than for patients under anæsthesia.

Dorsal position.—In this position the patient lies on his back horizontally with his head more or less in line with the trunk. Some form of restraint for the arms is necessary to prevent them slipping down at the sides of the table. A common habit is to place the hands palms downwards under the buttocks. This is unfortunately not without risk. Elderly patients, after a long operation, have sometimes developed gangrene of the fingers from pressure of the buttocks. What other means have we to fix the arms? One is Patterson's arm clamp consisting of two wide strips of metal whose curved ends hold the arms to the patient's side. Another device is a broad strip of canvas placed transversely across the table beneath the patient with straps and buckles at the outer ends to fasten round the wrists. An even simpler device is an ordinary roller towel also laid transversely beneath the patient. The ends of this are brought up over the patient's arms and tucked under the trunk thus providing restraint for the arms without undue pressure. Sometimes the arms are kept raised above the head. This position should be avoided as damage may be caused to the two lower branches of the brachial plexus by stretching against the first rib (Klumpke's paralysis). In the past year I have heard of two brachial palsies resulting from this posture. In one the anæsthetist withdrew an arm for intravenous therapy and kept it above the head for the rest of the operation. The result was a typical Klumpke's paralysis. The other case is less easy to explain as the upper branches of the plexus were affected producing an Erb's paralysis. Apparently the arm was not raised higher than the shoulder but was allowed to sag backwards. The table was also tilted sideways with the possibility that the head became

as were within easy reach. Radiotherapy must deal with the deposits within the chest and might as well cope with the apex of the axilla.

Dr. F. M. Allchin emphasized the value, as a pre-operative measure, of irradiation of tumours of the breast in Stage II cases. Those who have been fortunate enough to see the results of such treatment could not but fail to be impressed. The gross changes produced by interstitial radium treatment so ably carried out by Keynes and a few others had been repeated with X-rays. Many breasts thus irradiated had shown by histological examination after removal a complete absence of active cancer cells. These were what might be termed the more radiosensitive tumours. In the more resistant types shrinkage of tumours is not so marked and many attenuated malignant cells are found throughout the breast after irradiation. In both types the fact must be recognized that there are still potentially malignant cells remaining which may start into a period of activity at some future date. Hence the necessity for the operative procedure after irradiation before such activity begins. These remarks applied with even greater emphasis to the axillary glands which in his (Dr. Allchin's) technique are irradiated at the same time as the breast. As it was more difficult to remove all traces of malignant cells from metastatic glands the necessity for the clearance of the axilla became even more apparent.

Dr. Allchin added a plea for the education of practitioners and even of surgeons in the importance of establishing a diagnosis on every lump in the breast. The number of confident diagnoses of fibroadenoma and cyst in the breast which subsequently turned out to be carcinomata was far too great. Diagnosis on clinical grounds alone was too unreliable and should always be confirmed by histological findings.

[January 7, 1948]

Pathological specimens were shown as follows:

Intussusception of Ascending Colon from Carcinoma.—Mr. HAROLD DODD.

(1) Fibroma of Lung Removed by Lobectomy. (2) Ulceration of Œsophagus Due to Indwelling Ryle's Tube. (3) Photographs of Stomach Four Months after Ramstedt Operation.—Mr. IVOR LEWIS and Dr. J. H. HEGGIE.

Adenomyoma of the Duodenum (Hamartoma).—Mr. A. S. TILL.

(1) Post-operative Thrombosis of Deep Veins. (2) Neurinoma of the Vagus.—Mr. R. S. MURLEY.

(1) Pedunculated Intraperitoneal Metastases from Leiomyosarcoma of Stomach. (2) Obstruction of Ileum from Metastasis from Carcinoma of Colon. (3) Two Abnormalities of the Ileocæcal Valve. (4) Multiple Ulcerations of the Alimentary Tract. (5) Multiple Myelomatosis.—Mr. N. M. MATHESON and Dr. A. G. SIGNY.

Acute Non-specific Ileitis.—Mr. STANLEY AYLETT.

Lymphosarcoma of Ileum with Intussusception.—Mr. C. NICHOLAS.

Resection of Pancreas for Carcinoma.—Mr. L. P. ALLAN (for Mr. HAROLD DODD).

Extrarenal Hypernephroma.—Mr. FRANK FORTY.

Aortic Abdominal Aneurysms (2 Cases).—Mr. W. W. DAVEY.

Wilms' Tumour Treated by Radiotherapy.—Mr. J. P. HAILE (for Mr. ELLISON NASH).

Neurofibroma of Stomach.—Mr. F. N. GLOVER.

Intussusception from Secondary Bronchial Carcinoma.—Mr. LACEY (for Mr. D. H. PATEY).

magnus muscle by pressure on the long thoracic nerve, a condition sometimes seen in porters who carry heavy loads on the shoulder. They may also interfere with the venous return of the arm especially if it is supported at right angles for intravenous therapy. Recently I noticed an arm in this position assuming the mottled appearance of venous congestion and when I had eased the shoulder piece the arm rapidly regained its normal colour. A drip transfusion may become slow and stop under similar conditions. The explanation seems to be that pressure on the clavicle by the shoulder piece causes compression of the subclavian vein where it passes between the inner end of the clavicle and the first rib. The third method of fixing the patient in this position is by means of iliac crest supports. These are like modified shoulder pieces at the side of the table which press into the loins above the iliac crests. They should be fixed into position by the anæsthetist or surgeon as the nurses find the task difficult. Two disadvantages are associated with them. First, they are designed for use with the "Bart's" pattern of operating table and cannot be used on other tables unless modified. Second, they tend to bunch up the abdominal fat over the mid-line which may make operation difficult in stout subjects. Before leaving this position there are two points to consider. During spinal anæsthesia it is important to have a slight tilt head downwards to safeguard cerebral circulation. It is also important that the anæsthetist should be able to get the patient into this position in a matter of seconds in cases of sudden vomiting. The cases I have in mind are those with intestinal obstruction and those who come to the theatre with a full stomach.

Lithotomy position.—Case and Stiles found that the loss to vital capacity in this position was 18% and I was surprised to find this figure greater than that for the Trendelenburg position. Fortunately most patients needing this position do not require deep anæsthesia and can be operated on under low spinal or pentothal. Whatever pattern of support is used should hold the legs up as high as possible. This produces less pressure on the abdomen by the flexed thighs and it reduces the cramp of which patients sometimes complain when they are conscious. Sometimes a patient under general anæsthesia develops an ankle clonus when moved from the dorsal position into the lithotomy position. This is due to the patient's posture for the straps supporting the legs cause a sudden dorsiflexion of the feet when the patient is shifted, especially if this is done with a jerk. When the foot is extended the clonus stops and will not recur if the foot returns to its former position gently. Years ago this was called an ether clonus but I have seen it occur under pentothal and nitrous-oxide.

Lateral and kidney position.—With this position my chief worry is how best to place the patient's lower arm. If it is pulled too far backward he tends to roll on to his face and if pulled too far forward he tends to roll on his back. In the mid-way position the weight of the body presses on the under arm and often obstructs the venous return and in a short time the arm becomes mottled. If the patient is conscious he keeps shifting his shoulder to ease the discomfort and the surgeon is apt to complain. I have never seen any arm lesion result from this position but have an uneasy feeling that it may. I sometimes give pentothal to patients in this position and have wondered whether there would be delay in the drug reaching the general circulation but so far this has not occurred. Regarding the loss in vital capacity Case and Stiles found this was 10% for the left lateral and 12% for the right lateral position. With the bridge of the table raised for nephrectomy the loss is increased to about 14%.

Upright posture.—Most of the anæsthetics we give to patients in this position are for dental operations. The agents, at any rate for adults, are nitrous-oxide or pentothal though opinion is divided about the advisability of using the latter drug. The position of the patient is important. The head and trunk should be in alignment with the body nearly upright. Knees should be bent to a right angle with feet resting on the floor of the chair. In this position there is less chance of the patient slipping down while unconscious. If the feet are extended and resting against the bar at the end of the chair it gives him something to push against while under gas. The upright position must also be considered in relation to lung abscess. Two recent American textbooks make reference to the occurrence of lung abscess after operations on the nose and throat especially tonsillectomy. Here the complication is rare, the chief difference between us and the Americans is that many of their tonsillectomies are performed with the patients in the sitting position. In this posture septic material may drop downwards and enter the lungs through a larynx rendered insensitive either by local or general anæsthesia. Another point, chiefly of historical interest, concerning this position is on the use of chloroform. In the days when this drug was administered more frequently than it is now anæsthetists were warned of the danger of giving it to patients in the upright position. Both Hewitt and Hadfield in their textbooks issue this warning. Under chloroform the blood-pressure falls and there is the danger of sudden collapse or even death in this position.

Spinal anæsthesia.—The first point to emphasize is that the posture of the patient in the period immediately after the drug has been injected is the most important factor in determining distribution of the drug. It is simply a matter of gravity. If a heavy solution is introduced into a vessel containing a lighter solution the heavy solution will sink to the lowest

extended laterally away from the affected side and kept the tissues of the neck under tension. At any rate the patient had an upper arm palsy which lasted for eight weeks. If intravenous therapy is required during operation an arm should be extended at right angles and supported by a board. If this interferes with the surgeon the arms should be flexed with elbows resting on the sides of the table and hands flat on the sternum. The pyjama jacket can be turned back over the arms and its loose ends tucked under the elbows. Thus the arms are under control and it is not unduly difficult to get one out and replace it for intravenous therapy.

Pulmonary embolism is a perpetual bugbear to the surgeon and blame has recently been thrown on the veins of the calf as offenders in this respect. In the dorsal position the calves press directly on to the table and the veins of that area may become obliterated for a long period. Professor Lambert Rogers (1946) has prevented this by placing support behind the ankles and thus taking pressure off the calves. He has adopted this technique for over nine years and up to 1946 he had had no case of embolus in patients so treated. Except with tall patients the feet should not project beyond the end of the table. A case once occurred in which the table was moved close to the theatre window during an operation. Nobody saw that, at the end of the move, the patient's feet which projected beyond the table were touching a hot radiator with the result that severe burns were produced on the feet. In tall patients where projection of the feet is unavoidable one should place some soft material behind the heels to prevent pressure from the table.

Modification of the dorsal position is used in cholecystectomy. By raising a bridge in the centre of the table the trunk is extended and the ease of operation is increased. This is of more advantage to the surgeon than to the patient. In the paper to which I have referred, Case and Stiles found that the vital capacity is reduced by 12.5% in this position. In practice this position is tolerated by patients without undue difficulty but sometimes there are anxious moments. I once had to anesthetize a fit man of about 70 for removal of the gall-bladder. Induction was uneventful and when he was on the table the bridge was raised and the surgeon started work. During operation he became increasingly cyanosed despite added oxygen and his pulse became rapid and feeble. At length I told the surgeon we had better get him back to bed as soon as possible. By that time the gall-bladder was out and the surgeon was ready to close the peritoneum so the bridge was lowered. Within five minutes the pulse had settled down, the patient's colour had returned to normal, and operation was concluded without worry. I am quite convinced that the extended posture was responsible for this patient's distress. Another modification of this position often occurs after operation for hernia. The patient is lifted up and dropped upon an upturned porringer for the easy application of a spica bandage. Extension of the lower spine while the muscles are relaxed may give rise to trauma and I have seen a patient complain bitterly of backache after repair of hernia. As I can think of no reason to connect either the general anaesthetic or the operation with the backache I can only suppose that it was caused by the change of posture.

Trendelenburg position.—This is another modification of the dorsal position in which the table is tilted and the patient's head placed lower than the trunk. Originally the name was given to a tilt of 45 degrees but it now covers all degrees from a slight tilt to the extreme degrees used in operations on the pelvis. Case and Stiles found that diminution in vital capacity with this position was 14.5%. This was for a tilt of 20 degrees. In Altschule's paper the tilt was 22.5 degrees and impairment of respiration found to be 17%. While considering the effect of this position on respiration we may remind ourselves that the rocking method of artificial respiration relies on a tilt head downwards to empty the lungs. It would be interesting to have figures for the loss in vital capacity for a patient deeply anesthetized, at a tilt of something over 45 degrees, and with large packs in the upper abdomen. Personally I dislike a steep tilt especially in fat patients as I find it produces heaving respiration. I encourage the surgeons with whom I work to use as little tilt and for as short a time as possible. Other problems raised by this position are with the means employed to keep the patient fixed on the table. Two methods are in common use and a third which is less well known. In the first of these the patient's legs are fixed by straps round the ankles and the end of the table is dropped to a right angle thereby flexing the knees. If the table is tilted before the legs have been bent the patient may slide slightly and the bend at the knees may not correspond with the bend in the table. I know of two cases in which this position caused trauma. In one case pressure from the edge of the table produced paralysis of the external popliteal nerve with a resulting foot drop which lasted for two months. In the other case damage occurred to the popliteal artery and the result was gangrene and amputation. This was presumably due to the kinking of an already diseased artery for a long period. The other common method of supporting the patient is by means of shoulder pieces. These vary in pattern with different tables. Personally I feel that the anaesthetist should fix them or at any rate make the final adjustment. If left to the nurses they are often placed at different levels and at varying points of contact with the shoulders. Faulty application of the shoulder pieces may lead to nerve palsy. If placed too close to the neck pressure on the upper part of the brachial plexus may produce Erb's paralysis. They may also paralyse the serratus

Dr. H. W. Loftus Dale said that he, in common with Dr. Hasler, had observed the thin, small pillow on the theatre trolley, but liked it. It gave him the opportunity of saying to the patient "you are not comfortable, Nurse, get this patient another pillow", thus getting on good terms with the patient at once.

In cases where complete muscular relaxation was produced by curare or spinals, the use of a pillow to support the lumbar curve lessened ligamentous strain, so diminishing the tendency to post-operative backache.

Abdominoperineal excision of the rectum by the synchronous combined method done on an ordinary operating table necessitating the employment of a steep Trendelenburg tilt and the lithotomy position, plus a few abdominal packs, made it almost impossible for the anæsthetist to maintain adequate tidal exchange however hard he might try to assist respiration.

The prone position with pillows under the pelvis and legs abducted enabled hæmorrhoidectomy to be done under a "saddle area spinal" with much less congestion and hæmorrhage than is associated with the more commonly used lithotomy position.

Dr. R. J. Minnitt said that the subject of the posture of the patient was deemed so important that a whole chapter had been devoted to it in Ross and Fairlie's "Handbook of Anæsthetics" since it was first published, and this had been further elaborated by Dr. Gillies in later editions of the "Textbook".

There were three points he wished to mention. First, with regard to the bridge for the gall-bladder operation. One of the surgeons with whom he worked, experimenting upon himself, lay on the operating table for some time with the bridge up. The intense backache he endured afterwards led him to decide never again to operate upon a gall-bladder, using a bridge. Dr. Minnitt had been agreeably surprised as to how well this could be done, given good anæsthesia.

Secondly, he was once giving an anæsthetic to a patient in the lithotomy position, the arms being folded upon the chest. The surgeon gave the patient a push to correct the position, and in doing this one of the arms dropped over the edge of the table. Had the occurrence not been seen by a probationer a disastrous result might have ensued.

Thirdly, he had seen a patient fixed up in a Clover's crutch, about to undergo a gynaecological operation in a private house, lifted on to the end of a portable table, which tipped up and deposited her on the floor.

Dr. G. S. W. Organe instanced a large hospital with which he was associated where, as a result of persistent pressure from the anæsthetists, only one surgeon still insisted on the use of the gall-bladder rest, and where the gynaecologists themselves limited the degree of tilt in the Trendelenburg position. He mentioned, also, having seen Italian gynaecologists return the patient to the horizontal position before suturing the peritoneum, and abdominal surgeons apply pressure to the abdomen before drawing tight the last peritoneal stitch, in both cases with the idea of limiting the amount of air left in the peritoneal cavity.

Dr. H. J. V. Morton said that Dr. Hasler had rightly stressed the respiratory embarrassment which might be caused by the Trendelenburg position. The experimental work he quoted was of great interest in this respect. The whole question should, however, be reconsidered with due regard to modern anæsthetic practice. It could be shown that "assisted respiration" with a closed circuit apparatus effectively compensated any respiratory inadequacy brought about by the Trendelenburg position.

Mention should also be made of the use of posture in controlling sputum in thoracic surgery. For years it had been the custom to use the lateral head-down position in cases where bronchial occlusion was impracticable. Did the newer prone head-down position really offer noteworthy advantages? The muscles of respiration seem to fatigue readily in some cases in this position. Was there enough clinical evidence for the assertion that complications due to the passage of sputum to the good side were significantly less frequent with this method?

Dr. H. K. Ashworth said that he felt somewhat disquieted by Dr. Hasler's account of the opinion given to him by an official of one of the Medical Protection Societies on the legal responsibility of an anæsthetist for accidents arising from posture during anæsthesia. In his (Dr. Ashworth's) opinion no anæsthetist should ever neglect his primary duty of providing safe anæsthesia in order to place the patient in the posture required for operation. It should be a matter of courtesy, and not of responsibility, for the anæsthetist to perform this function. When the patient was arranged in the required posture for any particular operation, the surgeon was always asked if he was satisfied with the arrangements before the operation started, and Dr. Ashworth then felt that the surgeon's acquiescence discharged the anæsthetist's legal responsibility in this matter.

In one hospital in which a Resident Anæsthetist took part in the preparation of the patient, death took place while he was so engaged, and a rule was passed that in no circumstances would the anæsthetist take part in the preparation and posture of a patient for operation.

One unusual posture in which he was called upon to anæsthetize patients was sitting almost upright for the operation of cholecystectomy.

The President said that Dr. Hasler's paper displayed much common sense and information essential to the care of all patients during anæsthesia. He also pointed out that the present-day anæsthetists were called upon to do so many additional duties, such as positioning of patient, blood transfusion, supervision of tourniquets, &c., that he felt it necessary to guard against the possibility of anæsthesia becoming a minor incidence in the course of supervising the general efficiency of the theatre.

part of the vessel. If the fluids are miscible some degree of mixing will take place though it is possible to exercise some control over this. Supposing that 1 c.c. of heavy nupercaine is injected into a patient: If the patient is sitting at the time of injection and allowed to remain sitting for a few minutes low spinal anaesthesia will be produced high enough to do a closed operation on the bladder. If he lies on his side and the injection is made slowly to avoid mixing then if he remains on his side until the solution is fixed it is possible to produce unilateral anaesthesia with the underside affected. If on the other hand the injection is made with the patient on his side and immediately after he is placed on his back and given a slight tilt head downward then a bilateral anaesthesia will be produced to varying distances up the abdomen. Unilateral anaesthesia is easier to produce with a quick-acting solution like stovaine than with a slower one like nupercaine. The next point is that in my experience it is easier to perform lumbar puncture with the patient in the sitting position than on his side. I have never been able to satisfy myself why this is so. I have seen it suggested that a sandbag should be placed under the patient's loin to keep the spine straight but this would only provide a partial answer. I recently gave a spinal to a patient who was so fat that it was impossible to feel the tips of the lumbar spines while she was on her side. After several unsuccessful attempts I decided to have one try with her in the sitting position. In this posture I found it possible to palpate the spine and puncture was performed without difficulty. Another point to note is that extreme flexion of the spine is not always necessary for lumbar puncture. Sometimes I have introduced the needle too high in the space and on pushing it in horizontally have touched the spine of the vertebra below. Tilting up the needle is impossible as the tip of the spine above prevents this. By making the patient sit up slightly to extend the spine the skin over the back is relaxed and it is possible to approach the space at a slightly lower point without taking out the needle and making a second puncture. This enables the necessary tilt to be given to the needle. I have had numerous opportunities to give spinal anaesthetics to patients with fractures of the neck of the femur for insertion of a Smith-Petersen pin. It is impossible to get much flexion on the spines of these patients and only very occasionally have I had difficulty in performing lumbar puncture. The next point is that patients under spinal anaesthesia are liable to get a fall in blood-pressure and sometimes a rise in pulse-rate if their posture is changed, e.g. dorsal to left lateral position. Any change in position that is necessary should be done gently and if the patient is in a steep Trendelenburg position and the time comes to reduce the tilt it should be done in one or two easy stages rather than all at once. The reverse Trendelenburg should be avoided in these patients without first giving an intravenous injection of some pressor drug such as ephedrine or methedrine.

Miscellaneous points.—In the passage of an endotracheal tube correct position of the head is essential especially for blind intubation. Magill has taught us this for years. With regard to the prone position easy maintenance of anaesthesia is difficult unless one first passes an endotracheal tube. In the post-anæsthetic period posture is important. Elderly patients and those liable to pulmonary complications are raised in bed and not kept flat for longer than necessary. Patients in whom blood may accumulate in the throat such as tonsillectomy or dental cases should be placed on their side and kept there until round from the anaesthetic. After spinal anaesthesia patients should be kept with the feet slightly raised to prevent headache and finally those with accumulation of fluid in the air passages may have postural drainage.

Legal responsibility.—How does the anaesthetist stand in any legal action which might result because of nerve palsy or other sequela due to faulty posture? The secretary of the Medical Defence Union has kindly put the following facts before me. Each case must be decided on its own merits and there has been a tendency of recent years to blame the hospital and theatre staff rather than the surgeon. Nevertheless the responsibility for instructing the nursing staff rests in the first place with the medical staff who should keep an eye on them to see that they understand their duties. While the surgeon is usually busy getting washed and gowned or proceeding with the operation the anaesthetist is in a better position to see how the patient is placed on the table and to supervise such matters as the adjusting of shoulder pieces. In the event of an action for damages the surgeon, the anaesthetist, and the hospital may all have to appear together as defendants. In the event of a verdict in favour of the patient the anaesthetist and the hospital may well be held jointly responsible.

In conclusion I wish to express my thanks to Professor Kirk of the Middlesex Hospital Medical School for help with anatomical problems, to Dr. Forbes, secretary of the Medical Defence Union for help with the legal problems, and to those colleagues who have told me about their cases and thus helped to provide material for this paper.

and he may have no means of defending himself against these irregularities. This is the state of a patient in deep anæsthesia.

With such a completely malleable subject how shall we determine whether or not we are carrying his gaseous exchange too far from normal? How shall we know whether by this means or by other means we may be causing him damage?

We shall, of course, carefully observe his pulse, blood-pressure and colour for any evidence of anoxia. Assuming that this evidence is absent and that the patient is of good colour can we assume that we shall be removing the carbon dioxide from his body adequately? The answer is certainly in the negative. Roth, Whitehead, and Draper [1] describe how they gave to dogs doses of pentothal three times the amount required to produce respiratory arrest. These dogs had previously been breathing pure oxygen for about an hour so that most of the nitrogen had been eliminated from their bodies. After the pentothal there were no respiratory movements in the ordinary sense although there must have been small air movements due to cardiac beats. Placed in chambers ventilated entirely with oxygen these animals nevertheless survived by what the authors describe as "diffusion respiration" for periods of about one hour. Their colour remained good provided that they were surrounded by oxygen only.

The alveolar carbon dioxide tension rose, however, to very high levels of the order of 250 mm. of mercury. Nevertheless, they did not display the serious clinical signs which might have been expected.

A patient anæsthetized with cyclopropane may be in similar case. If the anæsthesia has proceeded for an hour or two and the bag has been emptied occasionally, most of his bodily dissolved nitrogen will have disappeared. Extremely feeble ventilation will probably keep him from cyanosis. Nevertheless very great accumulation of carbon dioxide might be occurring.

The effects of high carbon dioxide pressures upon man are serious, and many papers have been written upon this subject. As in all matters of anæsthesia, however, we have to determine whether the order of the effect which we experience is sufficient to produce grave results in the condition with which we are concerned. As so frequently occurs in anæsthetic matters, it is a question of degree.

The paper of particular interest is that of Dripps [2] in which he shows that the tidal respiration during close circuit anæsthesia may fall to a very low level without necessarily exciting the anæsthetist's attention. He records cases in which spontaneous respiration was present but was so inefficient that the alveolar carbon-dioxide pressure rose to 120 mm. or more. This rise was accompanied by about a 50% rise in the systolic blood-pressure and after the cessation of anæsthesia there was a precipitate fall of this elevated blood-pressure with symptoms of collapse sometimes called "Post-cyclopropane collapse".

On the other hand Seevers and Waters [3] have remarked that during controlled respiration by hand, excessive pulmonary ventilation is often produced, particularly by less experienced anæsthetists. This excessive pulmonary ventilation will, of course, bring about a fall in the alveolar carbon-dioxide pressure. You will recall that Yandell Henderson [4] contended that surgical shock was in large measure due to a low carbon-dioxide pressure caused by hyperventilation from pain, anxiety, &c. This theory is not now generally accepted but it is usually considered that a severe fall in blood-pressure will follow periods of forced hyperventilation. Once again we must regard the matter as one of degree.

Seevers and his co-workers found effects serious, but not perhaps so grave as we might expect. In typical cases which they examined the plasma pH rose by 0.31 above the anæsthetic level when the patient was breathing spontaneously. The systolic blood-pressure fell by as much as 20 mm. of mercury and the diastolic pressure rose by about 7 mm. of mercury. Tetany was not seen but there was some rigidity and exaggeration of superficial reflexes. Seevers claimed that when normal ventilation was restored these changes were immediately reversed. In this sense their results did not suggest a development of shock as such a condition would not be immediately reversible.

We must now consider the effects of pressure within the pulmonary tree as distinct from the effects produced by pressure upon the gaseous content of the lungs.

During controlled respiration the intratracheal pressure must always be positive. There will never be a phase of negative pressure within the lungs. Forceful artificial ventilation may increase the positive intratracheal pressure very considerably and there are three ways in which this might harm our patient: (a) By impairing the pulmonary circulation; (b) by a direct action upon the venous chambers of the heart which might prevent it from filling. Either of these effects might be reflected in some deterioration of the systemic circulation.

A good deal has been written on this subject much of it based upon hypothesis only, but recently there has been renewed interest in the matter. The main reason for this renewal of interest is the introduction of breathing of oxygen under increased pressure by aviators flying at very high altitudes.

Artificial Respiration

By E. A. PASK, M.D., M.A., D.A.

(Department of Anaesthetics, University of Durham)

ARTIFICIAL respiration concerns anaesthetists in two ways. First we use artificial or controlled respiration upon our patient during anaesthesia. Second we are sometimes called as consultants in the matter of resuscitation for emergencies where respiration has ceased. Let us begin by discussing the possible effect of controlled respiration upon patients during anaesthesia.

How do we institute controlled respiration? If we apply to the face of a conscious man a mask connected to a bag, with suitable means for carbon-dioxide absorption, he will breathe comfortably in and out of the bag provided that we make up the oxygen consumed. If now, at a moment when he is breathing out, we attempt to inflate his lungs by squeezing the bag we shall find our effort opposed by a marked muscular effort on the part of the patient. He will resist any disturbance of the rhythm of his breathing. The mechanism involved is usually called the Hering-Breuer reflex. It is through this reflex that the state of deflation of the lungs forms at least part of the normal stimulus to inspiration and the state of inflation of the lungs forms part of the normal stimulus to expiration. The reflex requires intact function of the vagus nerve for its occurrence.

Let us now consider what will happen if we carry out the same manœuvre on a man who is in a state of apnoea following a period of voluntary hyperventilation. Before we do so, however, it may be worth while to consider briefly the nature of this state, because it is not a very simple one.

If a normal subject voluntarily hyperventilates when breathing air, after a time further respiration becomes impossible and there ensues a pause before respiration starts once more. Before the end of this pause the subject will usually have become cyanosed. His blood is deficient in oxygen but he does not start to breathe until the level of carbon dioxide has climbed once more to normal or slightly above it.

Let us now suppose that we cause a normal subject to hyperventilate voluntarily when breathing oxygen. After a time respiration ceases and at the beginning of the ensuing pause his lungs will be substantially filled with oxygen. Quickly, however, a substantial proportion of the nitrogen dissolved in his body will be released by the blood into the lungs. In this way the oxygen in his lungs becomes diluted with nitrogen as well as carbon dioxide and water vapour, but even so the pause in respiration will last longer than in the previous case and when respiration starts again the subject will usually still be of quite normal colour. The stimulus to commencement of respiration appears to be almost entirely that of carbon dioxide.

In the third case let us assume that before the hyperventilation the subject has been breathing pure oxygen for a period of about one hour. In this way some 70% of the litre or so of nitrogen dissolved in his body will have been eliminated. Now, if he voluntarily hyperventilates on pure oxygen, the ensuing pause before respiration restarts will be much longer still. In subjects who have trained themselves to this procedure an apnoeic period of ten minutes is by no means impossible.

If we now take one of these subjects towards the end of his period of apnoea and attempt to inflate his lungs with bag and mask as we described previously, we shall find that the actual pattern of respiration can largely be dictated by our efforts. The total volume of respiration, however, still is not controlled by the operator unless altogether excessive pressures are used. If we increase the rate of our attempts to inflate the lungs we shall find that the volume of air that we can put into them decreases so that the total ventilation is determined rather by the subject's muscular activity than by the method or frequency of the artificial operation. This is true also, of course, of a conscious subject who has not hyperventilated if we use force enough to overcome the confusing action of his Hering-Breuer reflex.

When we attempt similar manœuvres of inflation upon a lightly anesthetized patient we shall find ourselves opposed by the Hering-Breuer reflex just as in the conscious man, indeed the irritability, so to speak, may be increased above normal. At slightly deeper planes of anaesthesia we find that we can increase the respiratory excursion each time that the patient inspires and in this way produce passive hyperventilation. Naturally as we are increasing the tidal exchange we shall increase the rate of absorption of the anaesthetic and the speed with which anaesthesia deepens. Thus whether by design, or by inadvertence, the patient will frequently become so deep that neither the nervous mechanism nor the chemical mechanism, whereby total ventilation seems to be limited, will operate. The patient comes into a state when we can do almost anything we wish with his respiration. We can over-ventilate him, we can under-ventilate him, or we can leave him without ventilation at all

carbon tetrachloride. Until spontaneous respiration has commenced, however, carbon-dioxide would appear to have no place in the treatment.

On the other hand the value of administering oxygen during the period of artificial respiration is clear. We have already seen that dogs can be maintained alive in an atmosphere of 100% oxygen, without respiratory movement. It is apparent therefore that if we can administer oxygen it will, so to speak, compensate for deficiencies in our technique of artificial respiration.

The methods of artificial respiration may be classified, briefly, as follows:

- (a) Prone pressure methods.
- (b) Supine pressure methods.
- (c) Postural methods.
- (d) Positive inflation and/or deflation of the lungs, either manually or by means of mechanical devices.
- (e) Methods of artificial respiration which depend upon the application of great stimulus to one or other of the respiratory reflexes.

The efficiency of the various methods has been much debated in the past but unfortunately the subjects used for experiment have nearly always been breathing conscious men or men who have voluntarily breathed themselves into apnœa. We realize now that little information of value can be secured on such subjects.

Few experiments have been carried out upon subjects or patients apnœic from anæsthesia or other cause.

Waters and Bennett [11] amongst others have reported on such experiments.

In 1942 Professor R. R. Macintosh and the staff of the R.A.F. Physiological Laboratory carried out further experiments on these lines using a deeply anæsthetized subject in apnœa believed to be due to deep anæsthesia rather than to acapnia. The respiratory tracings showed that considerably greater inflation of the subject's lungs was possible by pressure than was in fact obtained by most of the manual methods of artificial respiration. Thus the limitation upon ventilation appeared to lie with the methods rather than with the subject. From the records it would appear that either Schaefer's, Silvester's or Eve's, or any other rational method of artificial respiration, provided that it is intelligently carried out and a clear airway is maintained, can produce adequate ventilation of an unconscious apnœic subject. More important than the actual method chosen is the intelligent application of it.

If we may then assume that any method, within reason, will give us the necessary pulmonary ventilation, is there yet another factor to be considered?

In 1943 Cordier [12] drew attention to the possibility that methods of artificial respiration either hinder or assist the circulation. Cordier expected that methods which produced a negative pressure within the thorax, as for example Silvester's, might be expected to assist the circulation. Cordier made measurements on a cadaver and he found that the pressure changes within the ventricles and auricles were greater with a method such as Silvester's than with an intermittent pressure method. Cordier was cautious in interpreting these results and he advocated further experiments on curarized apes. Volpitto [13] and others, Thompson and others [14], have experimented on animals in respiratory and cardiac arrest to see whether artificial ventilation produced blood circulation. In general their results showed that the circulation produced was negligible in these circumstances.

The interval between cardiac arrest and a point when resuscitation by any means is impossible is extremely brief. It is unlikely that we shall often be able to intervene in this very brief interval. Therefore, it is perhaps of more importance to know what a method of artificial respiration can do to the depressed circulation of a subject who has already reached respiratory arrest but is not yet in cardiac arrest. Hemingway and Neill [15] have published observations on dogs under deep anæsthesia with arrested respiration. They first established that when ventilation with a respiration pump was adequate, the maximum oxygen consumption by the animal had been reached. That is to say, further increases in respiration did not increase the oxygen uptake. When they tried artificial respiration by a variety of methods, all producing ventilation above the adequate level, they found that there was a considerable difference in the oxygen consumption depending on the exact methods used. This suggested that a factor other than ventilation was involved and that a particular method might be superior, not only because of the better ventilation it produces, but because of some other effect. Hemingway and Neill suggested that this other factor may be the circulation rate. In most animals with which they experimented they found that while the circulation rate in a deeply anæsthetized subject respired by means of a pump was some 50% below the rate during light anæsthesia, if the same degree of ventilation was produced by a postural method, the cardiac output rose and almost reached the light anæsthesia level.

Clinical trials on fit men breathing under increased pressure of 8 to 15 mm.Hg showed that a proportion of them will, after a few minutes, show some circulatory failure or syncope. The incidence of this faint varied from one investigation to another but was of the order of 5% of individuals.

Animal experiment shows that a maintained positive pressure of 5 mm. of mercury has a variable effect upon the cardiac output, sometimes decreasing it and at other times increasing it. Kahn [5] and others have calculated that at 5 mm. increased pressure the work of ventilation is somewhat reduced. Above this pressure the work involved in respiration is increased. If the positive pressure is higher (about 20 mm.Hg) the venous pressure always increases, the systemic blood-pressure usually falls and the pulmonary blood-pressure rises. The effects are more severe if the chest is closed than if it is open [6, 7, 8, 9].

Carr and Essex [10] report that if dogs are ventilated to a positive pressure of about 15 mm. of mercury intermittently released to about 1.5 mm. of mercury, a certain number developed what they call fatal apnoea. This reaction was absent in vagotomized animals but was not modified by normal doses of atropine. Even small hæmorrhages produced a serious deterioration in the dogs' condition and in those which died there was acute parenchymal and subpleural emphysema. The serious effects were not noted, however, until the increased pressure had been maintained for three hours or more.

Beecher has rightly pointed out that though the effects of increased pressure on experimental animals may not seem to be very serious, they might well be much more significant in sick or injured human subjects. There are grounds for believing that the increased pressure within a closed system may be responsible for deterioration of cardiac output when the pressure has been maintained, during operation, for an hour or more.

In summary, if we allow a patient under anæsthesia to maintain spontaneous respiration of adequate volume, he can, so to speak, protect himself against grave abnormality of blood gases or intrapulmonary pressure changes. If we institute controlled respiration we must realize that we are usurping these important protective functions. The utmost care must then be taken to avoid damage. Generally speaking, unless there is good reason for abandoning it there seems to be a great deal to be said for maintaining spontaneous respiration.

Let us now turn to artificial respiration as used for the resuscitation of subjects who have ceased to breathe in some emergency. First, let us consider one or two points about the nature of our subject.

If a man is subjected to anoxia by being exposed, let us say, to an atmosphere of nitrogen, he will first of all hyperventilate. This hyperventilation may be very considerable, of the order of 30 to 50 litres per minute. Naturally carbon-dioxide is lost and the alveolar pressure of it falls very low. Later the effect of the anoxia will be to depress the respiratory function and respiration will become shallow, irregular and will eventually cease. If arrest occurred very abruptly following the period of increased breathing we might expect the subject to reach respiratory arrest with a low pressure of carbon-dioxide in the blood and the alveoli. On the other hand, if the period of depressed respiration before arrest is prolonged, carbon-dioxide must build up within the subject and he will reach respiratory arrest from anoxia with a high pressure of carbon-dioxide in his blood. In fact, animals asphyxiated with either nitrogen or helium stop breathing with high pressure of carbon-dioxide in the blood. Furthermore, a long period of ventilation at normal rate is needed before the carbon-dioxide level falls to normal.

In the case of subjects who have taken an overdose of a depressive drug there is every reason to expect a high carbon-dioxide level at respiratory arrest and this is found. In the case of drowning or asphyxiation by throttling, carbon-dioxide cannot escape from the body at all, and high pressure of carbon-dioxide in the lungs and blood will occur. In passing it must be mentioned that James and others experimenting on drowned dogs did not confirm this expectation. Their results showing unusually low carbon-dioxide pressures, must be regarded with reserve, I think, until they are further elucidated.

Therefore, in all the cases to whom we shall apply artificial respiration in emergency we may anticipate an existing high pressure of carbon-dioxide in the lungs and blood. There would seem therefore to be no place for the use of carbon-dioxide during the period of artificial respiration.

Once respiration has started spontaneously the state of affairs may be slightly different. If the agent which is causing the trouble is a volatile one which can be excreted through the lungs, then there is something to be said for maintaining a high level of ventilation even though it may be at some cost. For example, in carbon monoxide poisoning the rate at which the carbon monoxide is lost from the system is determined in part by the ventilation volume. In this case we might be willing to accept the fact that we were producing higher carbon-dioxide pressures and nevertheless administer carbon-dioxide for the sake of the increased ventilation. The same might well be true in the case of a volatile agent such as

[December 19, 1947]

DISCUSSION: SOME UROLOGICAL PROBLEMS IN GYNÆCOLOGICAL SURGERY

Mr. Everard Williams: *Vesico-vaginal fistula and the divided ureter*.—When the subject of vesico-vaginal fistula is under consideration the work of Marion Sims (and his successor Emmett) comes first to mind.

The problems that awaited his solution, his early misfortunes and later triumphs are well known.

In 1932 I had the opportunity of observing the work of that master urologist Latzko, of Vienna.

His wards in Elizabeth Hospital were filled with cases of urinary fistulæ, but they had not arisen from neglected confinements in slave labour, they were the sequelæ of gynæcological surgery in other clinics.

The latest figures from the Mayo Clinic reveal that of the cases of vesico-vaginal fistula under treatment 60% were of gynæcological and only 40% of obstetric origin.

The Sims' operation was evolved to deal with a fistula lying low near the urethra, usually of large size and adherent to the symphysis pubis, if adherent at all.

The fistula of gynæcological origin is found near the base of the trigone, is frequently multiple and, if adherent, the adhesion is to the ischial spine. It has an important anatomical relation—the ureter, which may be *involved* in the fistula, and which will assuredly be endangered in the repair. The same applied to many obstetric fistulæ.

Now it has long been known to urological surgeons that the bladder is an organ which takes kindly to surgical trauma. The mucous membrane is vascular and the wall muscular, so that surgical wounds heal readily, provided conditions are right.

In the year 1881, Trendelenburg was able to put into execution a plan of operation in a case of vesico-vaginal fistula that had been in his mind for some time. By means of a suprapubic transvesical approach, he attacked a high-lying vesico-vaginal fistula. As happened in the case of Marion Sims, this first operation proved unsuccessful, but undaunted and convinced of the merit of the operation, he persevered, later cases brought success, and in 1890 he published a case which he had operated on and cured in 1888.

In my modification of the Trendelenburg operation the patient is suitably anæsthetized and placed in the Trendelenburg position. The vagina is packed with gauze and a small volume of fluid is introduced into the bladder. The abdominal wall is divided in the mid-line. The bladder is exposed without opening the peritoneal cavity.

Stay sutures are passed through the bladder wall on either side of the mid-line and the bladder opened longitudinally. The necessary inspection is made and the diagnosis confirmed. A self-retaining bladder retractor with interior illumination, such as a Clifford Morson's, is introduced. The only other special instruments required are an angled knife of small size, like a cleft palate knife, two sharp hooks mounted on long handles, and a suction apparatus.

On the side on which the fistula lies, a ureteric catheter is passed into the ureter and its integrity established. This is left in situ throughout the operation.

TABLE I

Method	Rate/min.	Vol. of inspired air/min. c.c.	Oxygen consumption c.c.
Silvester	13	4,180	104
Schaefer	14.6	4,360	149
Eve	9	4,970	210

As yet no direct measurements of cardiac output have been made upon man during artificial respiration. It is possible, however, that similar variations to those noted by Hemingway and Neill do exist. Professor Macintosh, again working with the staff of the R.A.F. Physiological Laboratory, made measurements of the oxygen consumption of a man reduced to respiratory arrest by means of curare. The results are set out in Table I and it will be seen that although the ventilation with each of the three methods was similar, the oxygen consumption varied greatly from one method to another. It certainly suggests that ventilation should not be the only criterion in choosing a method of artificial respiration.

In advising upon a method of artificial respiration for emergency use, therefore, we shall first of all insist upon intelligent, efficient observation of the patient. The maintenance of a clear airway is of paramount importance. In some cases, where the personnel are not well trained, it may be better to use a method which will work fairly well provided that the textbook instructions are followed, rather than one which may potentially be better but which may require more intelligence and discretion in its achievement. As an example we might cite mouth-to-mouth respiration. There is no doubt of the efficiency of this method and it appears simple. Nevertheless intelligent observation of the patient is not easy, nor is it easy to maintain an adequate airway. The method is simple in that it requires no apparatus and it can be carried out in very confined spaces but it seems probable that considerable discretion is required if it is to be efficient.

We shall probably conclude that on the matter of ventilation it does not matter a great deal which of the standard methods we choose.

On the matter of circulation we shall probably conclude that matters are not quite so even. The variation in oxygen uptake between equal ventilation with different methods does suggest that they have varied effects upon the circulation. Final proof of this is not yet available.

Dr. W. O. Moore Ede enquired of Dr. Pask whether, provided he was fully oxygenated, he would prefer to be over- or under-ventilated, if he were anesthetized.

Dr. R. P. Harbord agreed with Dr. Pask's statement about the patient's condition during "controlled respiration", but thought it preferable to assess it after removing the mask (*Proc. R. Soc. Med.*, 1947, 40, 174). He felt that pulmonary ventilation was loosely judged by nitrous-oxide-oxygen standards instead of those of normal conscious subjects. Because it is difficult to estimate tidal volume by the visible alterations in spherical bags of varying capacity and content, he uses a test bag of 600 c.c. capacity—by-passed from the bag connected to a Water's absorber—as a guide in estimating the adequacy of tidal volume.

Dr. E. A. Pask, in reply to Dr. W. O. Moore Ede, said that if gross under-ventilation approaching standstill was contemplated then he would certainly prefer to take the risks of over-ventilation. It was not at present possible to assess the relative disadvantages of lesser degrees of over- and under-ventilation.

(2) *Good light*.—Except in the case of low-lying vesico-vaginal fistulæ, the surgeon can better visualize the important step in the operation, viz. the repair of the bladder wall; the repair of the vaginal wall is of small moment.

(3) *Combined fistulæ* (in the repair of).—When there is both vesical and ureteric injury, an abdominal approach is clearly essential. Both lesions can be repaired in one operative field and in one operation.

(4) *Failed vaginal operation*.—In surgical literature, cases are recorded of success with Trendelenburg's operation, after eleven successive failures with the Sims' operation.

(5) The abdominal operation is of much shorter duration than the vaginal operation.

Indications for the Trendelenburg operation: (1) All vesico-vaginal fistulæ of gynæcological origin. (2) High-lying fistulæ of obstetric origin, because of the proximity of the ureter. (3) Obstetric fistulæ, with adhesion to the ischial spine. (4) Failure, or recurrence after the Sims' operation. (5) Combined uretero-vaginal and vesico-vaginal fistulæ.

Miss Catherine Lewis: *Fistulæ of the bladder*.—Operation injuries, radium burns, fistulæ caused by malignant disease, and those due to rupture of a pelvic abscess. The majority of these fistulæ open into the vagina.

With regard to operation injuries, one type may be considered very briefly. I allude to cases where the patient has not been catheterized and there is a consequent risk of damage to the bladder while the abdominal incision is being made.

An injury to the peritoneal surface is not likely either. The peritoneum is closely attached to the postero-superior surface of the bladder over a small area only about the size of half a crown, and it is not likely to be compromised in the course of a gynæcological operation.

A much more likely accident is that the bladder may be injured while it is being separated from the cervix and the anterior vaginal fornix in the course of a panhysterectomy or even of a subtotal removal of the uterus. This part of the operation is often very difficult where the tissue planes are masked by malignant growth, where there is a marked degree of old inflammation with dense adhesions, or if simple tumours, fibroids or cysts have distorted the normal anatomy of the region. It is quite possible to make very large vesical wounds in such circumstances, but these are actually less dangerous than small ones as it is not likely that they would be overlooked at the time. Apart from a direct injury, the bladder wall may be so thinned during the process of stripping it from the vagina that sloughing will occur later, after the lapse of several days, when an ominous leak begins. In all these accidents the fistula usually opens into the vagina from the base or the trigone of the bladder.

There is another gynæcological operation in which the bladder is particularly vulnerable—that of plastic repair to the anterior vaginal wall. The two organs are intimately connected for a length of about two and a half inches, as is clearly demonstrated in the operation for total cystectomy, and it is not always so easy to separate them by blunt dissection; numerous small vessels and strands of fascia have to be cut deliberately. The bladder wall may thus be snipped, and the resulting wound is low on the base or on the trigone. It must always be borne in mind that, in any of these operation accidents, the damage may not be confined to the bladder but that one or both ureters may be involved. I believe that some surgeons appreciate the risk so much that they make a practice of inserting ureteric catheters prior to undertaking a difficult pelvic or perineal operation.

Fistulæ due to radium burns are still seen occasionally though, fortunately, they are rare. They follow radium insertion into the vagina for treatment of cervical carcinoma if a pack slips and the bladder is insufficiently protected from the irradiation. This may only result in comparatively minor damage such as mucosal ulceration, though this can be troublesome enough, but, if sloughing occurs, it may be extensive and finish as a vesico-vaginal fistula surrounded by devitalized and fragile tissues.

Malignant growths of the uterus or vagina tend to infiltrate the bladder and eventually to make an opening, either vesico-cervical or vesico-vaginal, which, naturally, goes on increasing in size. In this connexion it might be thought advisable, before treating an advanced condition, to make a cystoscopic examination in order to exclude vesical involvement. In an early stage this shows itself as a localized area of hyperæmia and possibly a little wrinkling suggestive of fixation, later a projecting mass with obvious signs of infiltration.

A pelvic abscess sometimes ruptures into the bladder and though, after a vesical crisis, its contents can be mainly discharged in this way, complicated fistulæ have been known to occur, opening on to the abdominal wall, into the vagina, or both.

The *symptoms*, once a fistula is established, are unmistakable—there is a constant leak of urine. The only difference between one case and another is that, in some patients, normal micturition goes on as well, whereas in others the whole of the urine runs away uncontrollably.

Assuming the fistula not to involve the ureter, a free dissection is made between the bladder wall and the vagina until healthy tissue is reached, all scar tissue is excised and the edges of the wound trimmed, while keeping it in *tension* with the sharp hooks and dry with the suction nozzle.

The vaginal wall is then closed with two mattress sutures tied from the vaginal side.

The fistula in the bladder is closed with interrupted sutures of fine non-chromic catgut, passed through mucous membrane and muscle wall. The bladder itself is not closed but sutured around a wide rubber tube. (A smaller size than a Marion tube is used.)

The abdominal wall is closed in layers in the usual way. There is no resort to catheterization. The rubber tube is changed on the fifth day and removed on the eighth day.

During the first three days, frequent bladder irrigation is carried out, say every three or four hours, through the abdominal tube, otherwise there is no special treatment.

Investigation of a case.—Towards the end of the first week after an extirpation of the pelvic organs, it may be found that the patient is no longer dry: that a fistula exists is all too apparent.

The immediate treatment usually advised is conservative, in the hope that spontaneous healing will occur. I doubt the wisdom of this course and think it is better to perform a cystoscopy at once and unless the fistula is of the smallest size proceed to perform suprapubic cystotomy and sew in a Marion tube and keep the bladder empty and at rest.

It may be argued that this may be unnecessary, because spontaneous healing may have occurred and the operation need never have been performed, but while the truth of this cannot be denied, it is my submission that it is looking at the problem from the wrong angle. A more difficult and hazardous operation at a later date may be averted, if this simple step is taken at once.

Presented with a case at a later date, the first point for decision is, when to conduct the repair. The practice of different surgeons varies in this particular, with recommendations to wait for the occurrence of spontaneous healing up to a year.

Once the track of the fistula is epithelialized, it will never heal and if it is not epithelialized it will have closed in a matter of weeks. The life of these patients is very miserable while the fistula is present, and unless it is of almost microscopic size, I cannot see any advantage to be gained in waiting longer than six weeks from the time of healing of the primary wound.

The preliminary investigations include a bacteriological examination, with appropriate chemotherapy if infection is present; intravenous pyelography and cystoscopy with ureteric catheterization on both sides. The latter step is, I believe, the only sure way of determining the presence or absence of a ureteric lesion.

A combination of uretero-vaginal and vesico-vaginal fistula may well be present and the excretion urography may show an apparently intact ureter, for with a large vesico-vaginal fistula there may be a retroperitoneal pool of dye and this may obscure the ureteric lesion, or the diagnosis may be incorrect.

In the presence of a ureteric fistula the Trendelenburg operation does not suffice and the operation must be transperitoneal for the repair of the ureter combined with transvesical closure of the vesical fistula—but the operation in general principles is the same. The vesical fistula is closed before the damaged ureter is dealt with.

The divided ureter.—Solution of continuity of the ureter may result from its division by the surgeon's knife, inclusion in a ligature, or necrosis of the wall through interference with the blood supply.

The first only of these happenings is apparent during the course of an operation; it may be deliberate as when the ureter runs through carcinomatous infiltration found to be more extensive as the operation develops than was anticipated when it began. The correct treatment in such circumstances is, I believe, to perform uretero-vesical anastomosis after mobilizing the bladder if need be, or failing this, as a second best, to perform uretero-colonic anastomosis. If, however, the ureter is accidentally divided, should the attempt be made to suture together the divided ends and perform anastomosis in that way? Textbooks of operative surgery suggest that this should be done, but I believe this view is wrong, because of the subsequent development of hydronephrosis. It is my submission that the accidentally divided ureter should be treated in a similar manner to that of the deliberately divided ureter by implantation into the bladder or colon, as the circumstances of the case dictate.

In pelvic surgery the ureter is in danger at two particular sites, viz. at the pelvic brim and near the ischial spine, in the latter location suture of the divided ends would be technically almost an impossibility.

The Trendelenburg operation has the following advantages:—

(1) *Good access.*—Anyone familiar with both routes knows that far better access is obtained with the transvesical than with the vaginal approach. This applies to a fistula in any part of the bladder.

such a case is probable—a two-stage operation is best; first an abdominal section and reimplantation of the ureter into the bladder and, later, repair of the vesical defect from the vaginal aspect. It may sometimes be possible, when the bladder is opened for the reimplantation, to repair the fistula from inside and it is, of course, most satisfactory to all concerned if this can be done, but it is not worth trying unless the chance of success is really good. As I said before, I have no experience of both ureters leaking into such a fistula, but should suppose that two if not three repair operations would be required. I believe it would be difficult to repair both bladder and ureter from the vagina, and should be glad to hear the experience of others in such cases.

Fistulae resulting from radium burns are very difficult to deal with. They are generally larger than operation wounds and the tissues are so devitalized as to have almost no healing capacity, so that even the most careful repair may break down. I am rather inclined to think that it is wise not to attempt to close the hole completely at one sitting, at all events if it is a large one, such as the size of a halfpenny, but to plan for two operations and try to make sure of a portion of success at each stage. If, in spite of everything, the fistula keeps on breaking down, it would seem best to abandon the attempt and to transplant the ureters into the colon.

There is nothing to be done locally where the tissues have been eaten away by malignant disease, and generally it is best to provide a portable urinal and leave events to take their course. But for a woman a portable urinal is very uncomfortable and difficult to adjust—it is almost necessary to design a new one for each patient—and in an occasional case ureteric transplantation might be considered as a palliative measure if the patient's general condition, renal function, and probable length of life would seem to warrant it. But it is such a serious operation, much more so than a palliative colostomy for instance, that the cases where it is justifiable are likely to be rare.

I do not think any definite suggestions can be made as to the treatment of a fistula originating in a pelvic abscess. Some of them are acute and some tuberculous, and the manifestations are too varied. Each case must be considered separately. The only rule, and this applies to any vesical fistula, is that the bladder must be thoroughly mobilized and firmly repaired, if the patient is to lead a comfortable life.

Mr. R. Ogier Ward suggested that he might usefully indicate in what manner a urologist could be of assistance in such cases. He alluded first to the treatment of very severe degrees of vesico-vaginal fistula of obstetric origin, such as were met with in native women. These were often so extensive that the anterior vaginal wall was absent and in its place only vesical mucosa was visible, and often the urethra itself was destroyed. In such cases he had seen the excellent results achieved by the surgeons in Nairobi where women came from the native reserves continuously—a testimony to success—for implantation of the ureters into the colon. None the less surgeons should not be too eager to perform this operation for which, it should be remembered, a healthy rectum with an undamaged sphincter was essential. Every means to effect local repair should first be tried, for transplantation was a severe procedure and a long term follow-up would show that some patients did not escape serious and perhaps fatal effects after a lapse of many months. In commoner and less severe cases of fistula certain preliminary examinations were important, particularly excretion urography, which would bring to light any ureter damage which might be present. If the vagina was packed with gauze and a flushing cystoscope used, the extent of the fistula and the state of the bladder could usually be accurately determined. Should a combined operation through bladder and vagina be proposed it was important to use a proper bladder retractor and to arrange for good illumination. The vesical mucosa must always be well freed from the scar at the site of the fistula and mobilized so that it could be closed without tension. This was the most important step in the operation and if it was well done the repair of the vaginal wall was merely a reinforcement of it, which, however, should not be omitted. He mentioned Swift Joly's operation which would be found useful in severe degrees of fistula. The peritoneum was opened, the apex of the bladder defined and the cavity opened just anterior to this; the incision through the bladder wall was then extended down to and around the fistula, the vagina being separated during the dissection. Stitches were then inserted to pick up the angles between the two organs, when tied these sutures had the effect of inverting the walls of each organ into its own cavity, other sutures being added to close the edges. In this, as in the direct bladder approach to the fistula already mentioned, it was better to maintain cystotomy drainage for a fortnight rather than to rely upon an indwelling catheter.

Mr. Ogier Ward, in reply to questions, said he had no experience of the operation of closure of the vagina so that the cavity became part of the bladder. When ureters were to be transplanted excretion urography was essential, this would often reveal duplication of the

This depends on the size of the opening; if it is a small one the escape does not keep pace with the renal output, and the normal function is retained though the patient is always wet. Often the position of the defect is indicated by an indurated area in the vaginal vault, though this may be masked by the scarring of a recent operation. This question of a partial or a total leak is very important to the surgeon as, in the first case, but not the second, the position and general lay-out of the fistula can be seen through a cystoscope and treatment planned accordingly.

Treatment.—Any injury to the bladder detected during the course of an operation should be repaired at once. The healthy bladder is a good healing organ, and the size of the opening does not matter, provided that it is mended immediately and well, and the bladder kept empty by drainage. Two layers of plain catgut sutures are used, and a self-retaining catheter inserted. Unless the wound is very extensive suprapubic drainage is not necessary. An indwelling catheter is certainly very uncomfortable to the patient, and some surgeons object to using one. It is apt to irritate the urethra and to cause vesical spasms but it is preferable to a suprapubic drain and the subsequent fixation which it entails. The catheter is kept in position for seven to ten days and, during that time, belladonna in some form may be given. Some operators prefer a suction apparatus to make even more sure of preventing tension.

If, however, the accident is unobserved at the time and if a small leak develops later (this occurs almost at once in the case of a direct injury, or in from five to ten days where necrosis supervenes), an indwelling catheter should be inserted at once, after which the wound may heal of itself. But, if a fistula once becomes established or if the original repair breaks down, a formal operation must be undertaken, and the only questions are—when to do it and what is the best method of approach. In the early days of its existence the edges of a vesico-vaginal fistula are ragged and friable and, especially if the opening is a small one and the drainage not very free, phosphatic concretions tend to form in and around it, and the escaping urine is thick and offensive. It is useless to attempt a repair at this stage; cleaning-up must be done first. Concretions, if present, are extracted from the vagina, and douches and urinary antiseptics given until all sepsis has disappeared and the edges of the defect are clean and well healed, probably in not less than three weeks' time. It is true that a good deal of scar tissue may form in the meantime, but this cannot be helped; at least there is a clean field to work in. On the other hand, operation should not be unduly postponed for fear of contracture of the bladder, not so much with small fistulae but certainly where there is a total leak. I remember a case where a fistula of two years' standing was cured but the patient, far from being grateful, complained that her bladder always felt full. 'And, indeed, it' had a smaller capacity than normal.

With regard to the method of approach this, to my mind, depends on the position of the opening in the bladder. If it is on the back wall but well above the trigone I like to close it from inside the bladder, but, if it is very low on the base, in the interureteric region or involving the trigone, I think a vaginal approach is best. This is my general rule, but complicated fistulae, possibly involving one or both ureters, must be considered individually according to the case. Simple operation fistulae are not likely to be adherent to bone. There is also the transperitoneal method described by Legueu, in which the peritoneal fold reflected from the back wall of the bladder across the vaginal vault is incised in the mid-line and the two organs dissected apart until the respective openings and the surrounding tissues are completely isolated from each other and the holes mended. This last point is of the utmost importance, whichever method of approach is chosen. There must be free undercutting and separation of the two organs, otherwise the repair will break down. Subsequent to the operation the bladder must be kept from filling for several days.

If one or both ureters are involved in the fistula it may be very difficult to diagnose the extent of the damage. I have never seen both ureters leaking into a vesico-vaginal fistula though I have known both to be divided during a difficult hysterectomy. With a large vesical defect it is impossible to fill the bladder for a cystoscopic examination, or, at any rate, for one which will give a clear view and permit of ureteric catheterization. It is obvious that the hole is there, and indeed sometimes a finger in the vagina passes through it, but one may not be able to make out the exact position or extent of the damage. In this case an X-ray—namely, an excretion pyelogram—is extremely helpful. If a ureter, perhaps slightly dilated, retains the dye an injury to it must be suspected. In cases where a routine cystoscopy is possible and the fistula, even though very small, lies anywhere near one of the ureteric orifices, that ureter should be catheterized. A catheter will not pass the site of injury, and a dye given intravenously does not appear from that side.

The treatment of a vesico-uretero-vaginal fistula must be planned according to the merits of each case. I am inclined to think that, if the vesical opening is at a low level—which in

such a case is probable—a two-stage operation is best; first an abdominal section and reimplantation of the ureter into the bladder and, later, repair of the vesical defect from the vaginal aspect. It may sometimes be possible, when the bladder is opened for the reimplantation, to repair the fistula from inside and it is, of course, most satisfactory to all concerned if this can be done, but it is not worth trying unless the chance of success is really good. As I said before, I have no experience of both ureters leaking into such a fistula, but should suppose that two if not three repair operations would be required. I believe it would be difficult to repair both bladder and ureter from the vagina, and should be glad to hear the experience of others in such cases.

Fistulae resulting from radium burns are very difficult to deal with. They are generally larger than operation wounds and the tissues are so devitalized as to have almost no healing capacity, so that even the most careful repair may break down. I am rather inclined to think that it is wise not to attempt to close the hole completely at one sitting, at all events if it is a large one, such as the size of a halfpenny, but to plan for two operations and try to make sure of a portion of success at each stage. If, in spite of everything, the fistula keeps on breaking down, it would seem best to abandon the attempt and to transplant the ureters into the colon.

There is nothing to be done locally where the tissues have been eaten away by malignant disease, and generally it is best to provide a portable urinal and leave events to take their course. But for a woman a portable urinal is very uncomfortable and difficult to adjust—it is almost necessary to design a new one for each patient—and in an occasional case ureteric transplantation might be considered as a palliative measure if the patient's general condition, renal function, and probable length of life would seem to warrant it. But it is such a serious operation, much more so than a palliative colostomy for instance, that the cases where it is justifiable are likely to be rare.

I do not think any definite suggestions can be made as to the treatment of a fistula originating in a pelvic abscess. Some of them are acute and some tuberculous, and the manifestations are too varied. Each case must be considered separately. The only rule, and this applies to any vesical fistula, is that the bladder must be thoroughly mobilized and firmly repaired, if the patient is to lead a comfortable life.

Mr. R. Ogier Ward suggested that he might usefully indicate in what manner a urologist could be of assistance in such cases. He alluded first to the treatment of very severe degrees of vesico-vaginal fistula of obstetric origin, such as were met with in native women. These were often so extensive that the anterior vaginal wall was absent and in its place only vesical mucosa was visible, and often the urethra itself was destroyed. In such cases he had seen the excellent results achieved by the surgeons in Nairobi where women came from the native reserves continuously—a testimony to success—for implantation of the ureters into the colon. None the less surgeons should not be too eager to perform this operation for which, it should be remembered, a healthy rectum with an undamaged sphincter was essential. Every means to effect local repair should first be tried, for transplantation was a severe procedure and a long term follow-up would show that some patients did not escape serious and perhaps fatal effects after a lapse of many months. In commoner and less severe cases of fistula certain preliminary examinations were important, particularly excretion urography, which would bring to light any ureter damage which might be present. If the vagina was packed with gauze and a flushing cystoscope used, the extent of the fistula and the state of the bladder could usually be accurately determined. Should a combined operation through bladder and vagina be proposed it was important to use a proper bladder retractor and to arrange for good illumination. The vesical mucosa must always be well freed from the scar at the site of the fistula and mobilized so that it could be closed without tension. This was the most important step in the operation and if it was well done the repair of the vaginal wall was merely a reinforcement of it, which, however, should not be omitted. He mentioned Swift Joly's operation which would be found useful in severe degrees of fistula. The peritoneum was opened, the apex of the bladder defined and the cavity opened just anterior to this; the incision through the bladder wall was then extended down to and around the fistula, the vagina being separated during the dissection. Stitches were then inserted to pick up the angles between the two organs, when tied these sutures had the effect of inverting the walls of each organ into its own cavity, other sutures being added to close the edges. In this, as in the direct bladder approach to the fistula already mentioned, it was better to maintain cystostomy drainage for a fortnight rather than to rely upon an indwelling catheter.

Mr. Ogier Ward, in reply to questions, said he had no experience of the operation of closure of the vagina so that the cavity became part of the bladder. When ureters were to be transplanted excretion urography was essential, this would often reveal duplication of the

ureter if it existed, even so this was a complication for which the surgeon must be on guard when actually operating. He had always supposed that the Sims' operation was unquestionably the best treatment for the usual case of vesico-vaginal fistula of obstetric origin such as was met with in civilized countries, but the combined bladder and vaginal method had an important place in cases of high fistula such as occasionally followed gynaecological operations, and also when operation by the vaginal route alone had been unsuccessful.

Professor G. Grey Turner: As Mr. Everard Williams has said we cannot allow ourselves to approach this subject without thinking of Marion Sims if only in admiration of his marvellous courage and perseverance. Let us always remember the primitive conditions of his environment and recall that he had to operate again and again on those brave women without the inestimable boon of anaesthesia.

The discovery of how to expose the parts concerned in the management of vesico-vaginal fistula by the adoption of the position which will be coupled with his name in perpetuity is enough to command our lasting gratitude. May I remind members that the story was delightfully retold by Professor Chassar Moir (1940, *Brit. med. J.* (ii), 773).

Of course since the time of Sims there have been many pioneers who have made notable contributions to the subject and I just want to recall to the Section that it was my old teacher, Professor Rutherford Morison, who first insisted on the importance of recognizing that the parts involved—the bladder and the vagina—must be separated from one another and individually repaired if interference is to have a reasonable chance of success (*Northumberland and Durham Medical Journal*, 1895, No. 213).

I wonder if in this audience I dare mention the early treatment of vesico-vaginal communications especially in obstetric cases, realizing that these are now quite rare in this country, and that in those parts of the world where they still occur with lamentable frequency, the patients are seldom seen until the fistulous track is well established. The parts involved have a very good blood supply and a great capacity for healing if they can only be kept clean and the urine diverted before the formation of cicatricial tissue binds the parts together and stabilizes the fistulous track. To attain these objects vaginal drainage should be promoted by raising the head end of the bed and by douches, fully realizing that it is not the composition of some wonderful douche that matters but the mechanical cleansing which it promotes. The urine should be diverted by catheter drainage via the urethra and by getting the patient to lie as much as possible in the face-down position. I trust that obstetricians will not condemn these suggestions out of hand but will try them.

In the prevention of surgical accidents to the ureter may I stress the importance of actually seeing that structure during a pelvic laparotomy by deliberately exposing it so that it can be gently thrust aside with the finger out of harm's way.

I have had a not inconsiderable experience of exposing the ureter over considerable lengths and I know how amenable that structure is to gentle handling.

The investigation and exact diagnosis of these fistula cases have been properly stressed and I would like to extol the value of milk as a bladder injection for demonstrating the site of the vaginal orifice of the fistula; it is better than a solution of methylene blue. A late ureteric fistula, one developing some days after surgical intervention, is probably the result of an area of necrosis which gives way and will probably be a lateral hole. Some of these will heal if a ureteric catheter can be slipped up beyond the opening and left in situ for some days. Meanwhile suction drainage from the site of the fistula will help.

Though those who have tried the method must be impressed with the value of the transvesical operation we should not allow ourselves to be blind to the wonderful success of the vaginal operation in careful and competent hands.

Of course the site of the fistula has a bearing on the choice of route and in those that are high lying the transvesical operation should be the method of election. In this field success is not due to luck but to the application of surgical principles with intelligence. I have often been asked what could be done when a ureter is inadvertently divided in some deep pelvic operation, not necessarily of a gynaecological nature. If both ends can be found and can be approximated without tension they should be directly united by suture and with very good prospect of success.

But it should be end-to-end union and the open ends of the ureters should be enlarged by being trimmed obliquely and then united by a few, not more than four or five, interrupted sutures of very fine absorbable suture material lightly tied. Any effort to make a close watertight union by a continuous circular suture is doomed to failure and will only result in stricture. Free unimpeded drainage by tube conducted to the surface by the most direct route is, of course, essential. If a ureteric catheter can be passed beyond the union it may be a help in

healing but I believe that its use should be reserved for cases where leakage persists for say more than ten days. The external drain should be removed in a week for by that time a track to the surface will be safely walled-off from the surrounding tissues and its contraction may assist in healing.

If easy apposition of the ends is not possible then implantation into the bladder is sound practice provided that it can be done low down so that the ureter in its new course can be kept extraperitoneal. If neither of these methods is possible two rational courses remain. First there is implantation into the large bowel which has proved wonderfully successful though it is not ideal, for some cases do develop an ascending infection which may seriously damage the kidney. (But how encouraging it was to hear a day or two ago from one patient whose ureters were transplanted nearly thirty-four years and another twenty-two years ago. Both are well, the first the mother of three children all born since the transplantation and the second recently happily married.)

The other plan is to bring the upper cut end on to the skin surface by the shortest route so that the problem of the resulting fistula can be deliberately tackled at some later appropriate time and probably by secondary bowel implantation. In any case the lower cut end can be safely left to take care of itself for its open lumen does not appear to cause mischief. Though it has sometimes been advised in the past, I would not now recommend that a divided ureter should be ligatured and allowed to retract into the retroperitoneal tissue though I can confirm that this has often been done without untoward result immediate or remote.

Some cases of ureteric fistula defeat the surgeon and just before leaving the Postgraduate School I had to carry out nephrectomy as the only possible method of dealing with a persistent fistula on to the surface. In that case the circumstances were so unusual as not likely to be met with in the lifetime of most surgeons.

Mr. C. Scott Russell: *Partial colpocleisis for the repair of the vesico-vaginal fistula following successful treatment of cervical carcinoma with radium.*—In the case described the fistula developed as a later sequel to radium treatment for cancer of the cervix. The fibrous avascular quality of the tissue surrounding the fistula made direct closure impracticable. A half-inch cuff of the vaginal wall below the fistulous opening was removed and the vagina closed with silver wire sutures. Continuous bladder drainage was instituted for ten days. After three weeks' time, during which there was no escape of urine, the sutures were removed. Unfortunately the retraction necessary to expose the last suture resulted in a partial breakdown of the repair; this was treated with temporary success by further bladder drainage. A tiny opening remains which it is hoped can be closed by a similar procedure.

Important points in the treatment of such cases:

- (1) Excision of the vaginal cuff at a level below that of devitalized avascular tissues, and the closure of the vagina without tension.
- (2) Continuous bladder drainage for ten to fourteen days.
- (3) The removal of the sutures with great care and gentleness.
- (4) No vaginal examination or coitus for three months.

Professor J. Chassar Moir said that every surgical technique capable of closing a vesico-vaginal fistula merited careful consideration. Naturally, the genito-urinary surgeon with his experience of bladder work felt more "at home" in approaching the lesion from above, while the gynaecologist felt surer of himself in approaching it from below. Nevertheless, it was obvious that if there was a choice of method, that procedure should be selected which would be least drastic or dangerous for the patient. Judged by this standard, the vaginal operation (based on Sims' technique) merited first consideration. To recommend the suprapubic approach for all fistulae (other than those low in the vagina) sounded to him like proposing to perform all tonsillectomies by a dissection through the side of the neck. He disagreed with the statement that high fistulae could not be satisfactorily dealt with from below. By suitable positioning of the patient, by use of suitable retractors and, when necessary, by aid of a generous episiotomy, adequate access could almost always be obtained. In some 50 vesico-vaginal fistula cases, gathered from different parts of the country, he had found that high fistulae (including those resulting from total hysterectomy or the Wertheim operation) had, in general, caused less trouble than certain types of low fistulae involving the vesico-urethral junction. Most of his cases had had many previous operations, including operations by the transvesical route. In spite of this, it had been possible to close the fistula by a vaginal operation. Strict attention had to be given to certain points of technique which the speaker then described with the help of lantern illustrations (*Edinburgh Medical Journal*, 1947, 54, 368).

Mr. V. B. Green-Armytage said that some years ago he had published in the *British Journal of Surgery* (1932) a series of vesico-vaginal fistulae treated by transplantation which were absolutely inoperable from below owing to their size and the fixity of their edges to the surroundings. These cases were seen in India and he was interested to hear Mr. Ogier Ward refer to similar ones that he had seen in Nairobi, for operators in this country had no idea what the young man in the Colonies or in the missionary field had to tackle in the way of obstetric fistulae. Therefore it was imperative before they went abroad that they should see urologists of note doing the colonic transplantation of ureters, for they might be faced by one of these inoperable huge obstetric fistulae almost on their arrival, and so should be able to tackle one *secundum artem*.

Sometimes on opening the abdomen it might be found quite impossible to do a ureteric transplant because of massive old pelvic inflammation and parametritis. The speaker had found this on occasions and could not elevate the ureter without grave danger of complete sloughing or tearing. In such a case might he put in a claim for colpocleisis, that is turning the vagina into the bladder by plastic closure of its introitus. This was not a difficult procedure and provided the patients could be seen now and then during the years, to be sure that no phosphatic stones were forming, they did well. He had found it wise to nurse these patients on the face or in full Sims' position with an indwelling self-retaining catheter for twelve days. The introital scar area was sprayed with acriflavine 1 : 1,000 alcohol solution four times a day and no external strong-smelling dressing allowed.

CORRIGENDUM

Joint Discussion No. 3, Section of Obstetrics and Gynaecology with Section of Radiology, *Proceedings of the Royal Society of Medicine*, 40, 907, December 1947,

DISCUSSION ON SOME ASPECTS OF SURGICAL AND RADIOLOGICAL TREATMENT OF CARCINOMA OF THE CERVIX

The following communication has been received from Dr. G. E. Richards, Toronto, as a correction to his paper "The Radiological Treatment of Carcinoma of the Cervix Uteri", p. 911:

"In my presentation of the results of the radiological treatment of carcinoma of the cervix uteri, figures were used for the purpose of comparing the effectiveness of modern radiotherapeutic methods with those of surgery. The figures used included those of Mr. Victor Bonney, in the compilation of which an error was made, which I hasten to correct, both in fairness to Mr. Bonney and in the interest of a strictly accurate comparison. The corrected figures are as follows:

"Bonney operated upon 500 cases selected out of a total of 800 diagnosed as cervical cancer, i.e. an operability rate of 62.5%.

"Of the 500 cases operated upon, lymph nodes were found *not* involved by cancer in 300 (60%), while in 200 (40%) lymph nodes were involved by cancer.

"Of the *gland-free* cases 159 patients survived five years, i.e. *gross* survival rate 53%. Deducting those lost to follow-up or died of extraneous disease, net survival rate 58%.

"Of the *gland-involved* cases 42 survived five years, i.e. *gross* survival rate 22%; net survival rate 23%.

"The figure 40%, quoted in my paper, was the over-all five-year survival rate and referred to all cases operated upon, not as stated, to Stages I and II only."

Snoring

By IAN G. ROBIN

THIS short paper is a plea for the more serious consideration of a complaint which is often a distressing physical and mental handicap. It may ruin a happy marriage, and in some parts of the U.S.A. it is considered justification for divorce. Up to date it has been treated as a comic pastime, and the unfortunate adult sufferers (and even more the agonized relations and associates) have to bear with it in fear of ridicule.

There is almost no world literature on the subject except for the Japanese observers who have devoted some time to it. But we can gain some useful information on the matter from recent work by anatomists and orthodontists who have been studying the mechanism of palatoglossal movements and their relationship to mouth breathing. I am indebted to Dr. J. Whillis, Mr. Gwynne Evans and Mr. A. Nove for most helpful personal conversations.

Definition.—Noisy respiration during sleep may be produced during inspiration and expiration by various structures in the respiratory tract. I propose to limit snoring to sounds made by vibrations in the soft palate and posterior faucial pillars during sleep. This definition excludes sounds made by laryngeal structures including the epiglottis, by the tongue, cheeks, lips or nostrils. Snoring is usually produced during inspiration through the mouth. Sometimes, however, breathing is through the nose (Negus says this occurs in some "gifted individuals"). A short inspiratory snore through the nose with the mouth open may be called a "snort" and some persons are addicted to a series of snorts.

Snoring is involuntary: it stops as soon as consciousness is regained.

Mechanism.—Whillis has shown very clearly by means of a pharyngoscope that the vibrating part in a snore is the thin edge or velum of the posterior faucial pillars. He proved that a reservoir of air is necessary in the nasopharynx: if this space is completely filled the velum cannot vibrate. He also demonstrated that the velum is set in vibration during respiration (usually inspiration) when a "critical point" or position is reached in the relative position of the tongue and soft palate. But not only is it *position* that influences the vibrating parts, it is the *texture* of the velum, and this depends on the tone of the musculature of the glossopharyngeal arch, and the thickness of the tissues (especially the mucosa). The actual pitch of the sound is determined by the so-called "flutter-ratio" of the faucial pillars: Strauss likens the physics to a fluttering flag in a wind—any increase in the force of air intensifies the noise but does not change the pitch. This depends on the density, elasticity, and size of the vibrating part.

Position of the soft palate.—When sucking, the infant's soft palate is in close apposition to the back of the tongue (fluid being squirted intermittently back into the pharynx). A suckling is therefore unlikely to snore during sleep, as the relation between tongue and soft palate is unlikely to change. When the chewing habit develops the soft palate is raised away from the tongue. If mouth breathing occurs for any reason, the palate is free to vibrate. In adults the position is regulated by the tone of the muscles as well as the amount of airway in the nose. Nove maintains that a short ramus of the mandible makes the palate lie away from the dorsum of the tongue.

Position of the tongue.—This plays some part in determining the "critical point". If during mouth breathing the dorsum is arched, or falls back, then it will be near to the velum of the fauces. The position of the head may govern that of the tongue. Sleeping on one's back is considered a common cause of snoring, because the tongue falls back more readily. The act of swallowing (the mechanism of which is so admirably described by Negus, 1942, *Proc. R. Soc. Med.*, 36, 85) actually inhibits that of snoring; there may be complete cessation or resumption, depending on whether the tongue returns to the snoring or "critical" position, and also whether the reflexes to be described are inhibited.

With regard to the position of the tongue there seems to be no influence from the presence or absence of teeth or dentures in the production of snoring. On the other hand an orthodontic "monoblock" or "Andresen" splint can mould the dental alveolar pattern (probably without changing the basal bone one) and so lead to less mouth breathing.

Tone of the glossopharyngeal musculature.—This has a governing role for the "critical point", as it decides the positioning and elasticity of the parts. Gwynne Evans and Whillis agree that there is a "central reflex" determining the control of the muscle groups, i.e.

muscle behaviour is patterned by the C.N.S. These patterns are inherent developments of inborn conditioned reflexes, predestined in foetal life. An inhibition of central control will thus upset the muscular balance. Gwynne Evans associates immobile palatolingual with immobile orofacial musculature, as in so-called "adenoid facies".

It can be put forward as a plausible explanation of snoring that during sleep there is a fall in adrenal secretion: this leads to a rise in parasympathetic over sympathetic action, and therefore a diminution of tone in the palatal structures.

In sleep there is said to be a rhythmic variation of depth: at first considerable depth, then lighter sleep and then before waking another increase in depth. If this is true one would expect snoring to occur more readily early in sleep and then just before waking. Actually severe sufferers snore all the time.

In anesthetized patients it has been said that a real snore does not occur—but this is not true—at any rate sounds just like snoring are heard. Dr. Vevers of the Zoological Society has told me that he has heard a chimpanzee snore under an anæsthetic.

Other factors influencing the position and tone of the glossopharyngeal structures.—Certain conditions other than that of nasal obstruction lead to slight œdema of the palatal mucosa, or loss of tone in the muscular velum. Slight pharyngitis from working indoors, and from smoking, obesity, plethoric tendencies, and allergic manifestations have all been listed as aggravating causes. One observer has described snoring as one of the diagnostic signs of leprosy of the pharynx; if this were so, one would expect any granulomatous condition in the pharynx to lead to snoring. That a mobile palate is essential for snoring is utilized by speech therapists in the "snorting test" in training cleft-palate patients.

I must mention that in America some prominence is given to the psychological aspect of causation. An article entitled "Does a contented person snore?" shows the trend of thought. It is considered that some snorers stop the habit when on holiday, and others have cycles of snoring periods regulated by psychological and endocrine factors. Personally I think this unlikely, but Gwynne Evans' theory of "central reflexes" makes it not impossible for basal or even higher centres to decide if and when we snore.

Ætiology.—At first thought it appears that the explanation of snoring would be simple enough. Any organic condition causing nasal obstruction would lead to mouth breathing, and a snore would be unavoidable. But this is not so: mouth breathers do not all snore. Causes must be divided into organic and functional or, better, dysfunctional, and although the main predisposing cause may be organic there is usually a dysfunctional cause as well.

A. Organic causes.—(1) *Nasal obstruction:* It is often the minor degrees of obstruction which lead to enough mouth breathing to initiate snoring, e.g. slight deflection of the septum, collapsed alæ nasi, or moderate mucosal congestion.

Dr. Vevers tells me that although he has never heard a wild wolf snore, many domestic dogs, all descended from the wolf, do so. He imagines this occurs in breeds with malformation in the nose and nasopharynx, caused by such conditions as achondroplasia, as seen in pekinese, &c.

(2) *Pathological changes in the pharynx* may make the soft palate and faucial pillars more liable to be in a suitable physical state for snoring to be initiated.

B. "Functional derangements"—or "*Dysfunctions*"—of the "central reflex" governing the tone of the glosso-pharyngeal musculature.

Age-groups.—There are three main eras of snoring: in the child, the adult and the elderly person. In children the majority are cured by removal of their adenoids and tonsils. The exceptions to cure include the persistent mouth breathers of "functional" origin and those with infective or allergic rhinosinusitis.

The adult who starts snoring usually does so from some organic cause. Women snorers appear to be as numerous as men.

The largest group of sufferers are elderly men and women. Lack of tone seems to be the fundamental cause.

TREATMENT

A. Irrational methods.—Chief amongst these is amputation of the uvula, which used to be a popular practice. Removal very rarely gives much relief, but it may modify the degree and pitch of the snore.

B. Rational methods.—(1) *Remove or prevent nasal obstruction*, and so allow for cessation of mouth breathing. In some instances simple decongestive nasal drops before retiring will allow a peaceful night. In others various nasal operations may have to be performed. Benadryl is useful for some persons.

(2) *Change position of head* to prevent tongue falling back. Many persons snore only when on their backs, and on some occasions the uncomfortable procedure of a cotton reel sewn into the back of the pyjamas is efficacious.

(3) *Alter position of tongue, soft palate and/or jaws*, by breathing, swallowing and phonetic exercises, or by orthodontic "splints". The former aim at training the central nervous system to regain proper neuromuscular control. The latter alter the shape of the mouth and thus try to guard against the tongue and fauces falling into the "critical" position.

In all these three groups it is necessary to regain proper central control of the soft palate, and break the habit of an inverted reflex.

(4) *Keep mouth closed during sleep*: This is done by wearing an "Andresen" splint (which is well tolerated by most children, but less so by an adult) or by the simple expedient of a strip of adhesive plaster across the corner of the mouth. After a short time this is well tolerated by many patients. An adequate nasal airway is of course essential.

C. *Altering texture of soft palate and faucial pillars*.—Injection of a sclerosing solution into the pillars is advocated by Jerome Strauss, though this enthusiastic surgeon has not been able to claim a high percentage of cures so far.

However, I feel we surgeons may have helped many potential future snorers by our effort at removal of their tonsils and adenoids—leaving them with nothing but a fixed fibrous band instead of nice mobile soft palate and faucial pillars!

CONCLUSIONS

Snoring is a symptom of unbalanced breathing, caused by a combination of several physical conditions, some brought about by pathological and other by physiological disorders. Remedies must aim at preventing all these causes and not only one.

Film Showing Organic Disorders of the Larynx.

G. H. Bateman said that some months ago he had shown the Section a film illustrating bronchial neoplasms which Dr. Paul H. Holinger, of St. Luke's Hospital in Chicago, had taken. Dr. Holinger had now sent him a film entitled "Organic Disorders of the Larynx", which had been prepared from Dr. Holinger's own cases and had been sub-edited and annotated for showing to medical students and speech therapists. He had had the opportunity recently of talking with Dr. Holinger about his method of taking films by indirect laryngoscopy. The patient sat upright facing the operator who used the same camera and apparatus as was used for the direct pictures. The laryngoscopic tube was used and a mirror obliquely disposed at the end of this tube. Thus the mouth did not appear in the films as the view is confined to the mirror and its reflections. In direct laryngoscopy the mirror was removed and the laryngoscope tube introduced in the ordinary way, with the patient having his back to the surgeon. All the pictures were taken under local anaesthesia.

The result of this change of position of the patient is that the right cord will be on the right of the screen in the direct pictures and on the left in the indirect pictures.

A considerable range of pathological conditions of the larynx is shown and the treatment mentioned though no details of treatment are given in the film. The colour is very accurate and the film is an admirable method of demonstrating the pathology of the larynx to students.

Bell Telephone Film of the Laryngeal Movements.

V. E. Negus showed a film taken by indirect laryngoscopy with an ultra-rapid camera. The pictures were taken at 4,000 frames per second and slowed down to normal rate so as to show the laryngeal movements in slow motion. Mr. Negus said that this film differed from the beautiful film they had just seen in that it showed the normal mechanism instead of diseased states.

Many of those present, like himself, had no doubt made use of the stroboscope, from which a great deal of help could be obtained in observing the laryngeal mechanism. On the evidence of the stroboscope was based a certain amount of the criticism he would make of the film. The stroboscope consisted of a perforated disc so rotated in front of a lamp that the light could be interrupted a certain number of times per second; the speed could be altered at will. If the speed were 200 times per second, for example, it was possible to illuminate the larynx at exactly the same rate as that of the sound produced. If the pitch were at the rate of 200 vibrations per second the vocal cords for 1/400th of a second would be moving towards the mid-line and for 1/400th of a second away from the mid-line. If only one phase were illuminated the cords appeared to be stationary. By varying the speed

the light of the stroboscope could be made to interrupt at 201 times per second, while the patient was still phonating at 200 double vibrations. Every time, therefore, the cords would be illuminated a little sooner or a little later than before, and it was possible to see, for instance, whether the arytenoids came firmly together or whether they remained separated; so that actually an even slower picture could be obtained than with this film.

The normal mechanism of phonation consisted of approximation and separation of the vocal folds. In this the arytenoid cartilages should come together and should remain firmly apposed and should not vibrate. There were theoretically two ways of raising the pitch: One was by *stretching and tightening the cords*; and the other by *increased contraction of the arytenoid muscles*, whereby the elasticity of the glottic margins increased and the vocal cords therefore recoiled more rapidly than when the muscles were less powerfully contracted. When this contraction took place the pull of the adductor and tensor muscles was so strong that the fold was shortened. The rise of pitch depended on the increase of elasticity of the thyro-arytenoid muscles, due to their increased contraction, and not on stretching of the cords.

A second point was the position of the arytenoid. How the arytenoid cartilage remained in a certain position would be shown in the film; also the eversion of the vocal folds, which did not merely separate in a lateral direction from each other but had a sort of rolling movement. Also, as the vocal cords shortened, the aryepiglottic folds would be observed coming forward. Looking from above, the epiglottis appeared to tilt forward and to display more of the vocal fold as the pitch rose.

A third part of this film showed how the glottis was blown open. If the thyro-arytenoids contracted and held the cords together the glottis would suddenly be blown open on phonation, and then the elasticity of the glottic margins was sufficient to bring the folds together again, the repetition of this process producing a sound of a fixed pitch. In some cases it was only a short part of the glottis that opened. In another part of this film would be seen the mechanism of whispering.

If by some means there was lack of apposition of the arytenoid cartilages, and if the vocal processes were kept slightly apart, there would be a disturbance in the vibration of the cords. If the posterior ends were not kept close together the vocal cords would bang together and impinge unduly at their centres. In the higher pitches it would be noticed that only the margin of the cords separated, without the eversion which was shown in the lower pitches. The last part of the first reel showed vibration at 850 vibrations per second.

One point of interest in the second reel was that one vocal cord was seen to be vibrating *more than the other*. It was possible for the patient to produce a sound almost entirely by vibration of one vocal cord, the other remaining stationary. It might be because of this that there were very few singers with completely pure tones. Another effect shown was the rise of pitch when the patient breathed helium. If helium with oxygen were given to a patient with dyspnoea it could be determined whether it were given efficiently by the manner in which the pitch of the voice rose.

V. E. Negus added that in the textbook "Diseases of the Nose and Throat", by the late Sir StClair Thomson, fig. 33 showed the imperfect view of the larynx obtained by the beginner because the epiglottis overhung part of the vocal cords and made the view incomplete. If one held a laryngeal mirror against the hard palate and got the patient to make the sound "E" it was often possible to see the whole of the vocal cord, including the anterior commissure, without causing the patient to feel sick. The mechanics of the elevation of the larynx were somewhat complicated. As the pitch rose the larynx was usually elevated to a certain extent and brought up towards the hyoid, and in doing so was tilted so that the vocal cords came to be more at right angles to the axis than at low pitches.

Mr. Forster had spoken of a phenomenon of the right arytenoid in phonation being well in front of the left. One might be led into error if one based a supposition of paralysis on the fact that one vocal cord did not move as well as the other; it might be simply a functional process. In all cases of functional disability the Wrisberg cartilage would be upstanding and in the usual position, but in all cases of organic paralysis, the posticus being the first to be affected, this cartilage would fall forward, and the aryepiglottic fold would obscure the vocal cord. It was quite easy to distinguish between the two conditions. On the one hand the patient might have a mediastinal mass, or else the whole laryngeal condition might be functional and due to a slight disorder of muscular effort; it was difficult for the contraction of the two sides of the larynx to be equally balanced.

The vocal cords themselves were of such small mass that they could not produce much sound. The sound was not made by vibrations similar to those of a string, but by the interruption of the air current into puffs. Only by the modification and amplification of resonators was speech and voiced sound produced.

Progress in the Treatment of Mastoid Infection and some of its Complications

PRESIDENT'S ADDRESS

By DONALD WATSON, F.R.C.S.

THE discovery of antibiotics has simplified and, with the advent of others, will increasingly simplify the treatment of acute conditions of surgery.

In his Presidential Address two years ago Graham Brown (1945) said:

"I believe the opportunities for mastoid surgery are gradually decreasing in proportion as the prophylactic measures against the incidence and spread of aural disease increase. Indeed, the time may not be far distant when intracranial complications of otitic origin will be considered rare phenomena."

My introduction to mastoid surgery was in 1920 in Edinburgh, where I worked for two years under Mr. J. S. Fraser.

His method of treating the acute mastoid cavity, after a most thorough removal of all infected bone, was to cleanse it with hot hydrogen peroxide and to pack the wound with iodoform gauze, leaving an adequate drain at the lower end after closure of the rest of the wound. The pack was removed on the third day, the wound was repacked and continued to discharge more or less for three to four weeks before healing took place. This ideal was not always attained: often the wound broke down, when eusol syringing was carried out twice daily. An infected, broken-down wound meant prolonged treatment, sometimes of many months' duration.

Going to Bradford in 1922, for four or five years I tried other methods then practised, such as the blood clot method—closure without drainage. This was very unsatisfactory, as the wound usually broke down. Then there was the method of leaving the wound almost entirely open, packing it, and allowing it to heal by granulation tissue from the bottom. This was a tedious method, but it certainly obliterated the cavity, and there were no recurrences. The subsequent depression over the mastoid is unsightly. Nevertheless, it is a method practised even to-day in certain clinics.

Next came the use of various antiseptics with packing. Of these T.C.P., first produced about 1922, was the most successful in my hands.

It was in 1928 that I discarded bipp and reverted to the Carrel-Dakin method of flushing the wound with eusol and drainage by rubber tubes. This method was employed almost exclusively until early in 1933. It was a safe method—took time to do the dressings, but obliterated the cavity. T.C.P. was used as a final lotion for dressing the wound.

In the February of 1933 a severe influenza epidemic occurred and, at its height, no less than 53 cases of acute mastoiditis were in hospital at the same time. Most of these were severely infected, some had complications, and the labour of dressing them was a tremendous strain on our nursing resources.

I decided to go back to using bipp in the liquid form, with a small gauze drain at the lower end of the wound. The bipp in the paste form used a few years previously was too solid and I am sure it caused the recurrences. The liquid bipp plus drainage for two or three days greatly lessened the number of recurrences.

This bipp method, published by Mr. Herbert Tilley (1919), Holt Diggle and Gilhespy (1921), supported by Macnab of Johannesburg and others, was the most successful in my hands and also in the hands of other surgeons, and I have used it until 1944. The great majority of cases were discharged, with the wound healed, in a fortnight. Packing the wound was dispensed with.

Secondary suture.—When there was osteomyelitis of the squamous temporal and of the occipital bone, it might be necessary to enlarge the mastoid wound by one or more radial incisions, backwards or upwards and backwards.

In such wounds and also in widespread and severely infected cases, a bipp pack left undisturbed for five or six days enabled one to do the secondary suture, which was so important. The wound must be closed in five to six days, otherwise, owing to shrinkage and curling of the flaps, it may be impossible.

Even with bipp sometimes a child's wound would not heal. Occasionally I gave these tardy cases a weekly dose of tuberculin in a glass of milk, an hour or so before breakfast. This has a most beneficial effect on these slowly healing wounds.

To-day the universal practice is to dust the mastoid wound lightly with penicillin and sulphathiazole powder and close it, except perhaps for a small gauze drain at the lower end left in situ for a couple of days. Most cases are discharged healed by the twelfth day with a dry ear. In severe infections, the giving of sulphonamides and penicillin is an added safeguard. This modern treatment has shortened the stay in hospital tremendously. Whether the aditus remains open and recurrences are to be expected more frequently, I am doubtful, but the great saving of time and worry outweighs this possibility. Even secondary suture in mastoid surgery will, I believe, also become a relic of the past.

Lateral sinus thrombosis.—In these days of antibiotics and chemotherapy cases without cerebral complications should all survive.

With regard to ligation of the jugular vein: years ago, Mr. Ballance said there were occasions demanding ligation, and there were occasions where the local condition in the sinus could be dealt with efficiently without ligation. A more rational opinion one could not have on this problem. I was always prepared to ligate the vein if occasion arose, as I am firmly convinced of the efficacy of this procedure. Even with the aid of chemotherapy I should not hesitate to ligate the vein if the case had symptoms of pyæmia with infarction of the lung. Otherwise treatment of the local condition of the sinus is all that is necessary.

To obtain the best results in lateral sinus cases, surgeons have had to do the dressings themselves for many days, but we got good results, even as high as 80% recoveries in cases without cerebral complications.

The accompanying septicæmia is the danger in sinus thrombosis. Antitoxic sera of all kinds have been tried. The best, I believe, was the scarlatinal antitoxin. Quinine was also used. It did one good thing. Frequently a fixation abscess occurred at the site of the injection. One was always pleased to see this. These cases entail long and tedious treatment and careful observation.

I have opened 11 abscesses including an infected knee-joint and an ankle-joint in one boy, and he recovered with no disability except a stiff knee.

Lateral sinus thrombosis cases have given us many interesting struggles. Pus in the internal jugular vein was not a rare occurrence.

With the continuation of rigors or swinging temperature—a common occurrence—one has frequently traced the lateral sinus back to the torcular Herophili before effecting a cure, this process requiring three or more operations. Mr. J. S. Fraser always packed the interior of the open sinus with iodoform wool, but I understand some surgeons did not believe in this rational procedure.

I have had only one case of cavernous sinus thrombosis as a complication—a man aged 28. I am informed that after his recovery he lived for a further six months and died at home with symptoms of brain abscess.

Perhaps my most interesting case was one in which an abscess developed at the root of the neck, just between the clavicles. I waited before opening and packing this one. On removing the dressing two days later I was alarmed when I looked inside, as there was no reaction in the walls of the cavity and everything seemed to be pulsating. I repacked that cavity with bipp and left it. This child of 5 had an interesting reflex. Her lateral sinus had been opened almost to the torcular, and each day as I dressed her and touched the sinus wall she complained of pain on her nose—a reflex through the meningeal branches of the fifth nerve. She eventually recovered after having been on sulphathiazole continually for six weeks and having taken nearly 800 grammes.

The actual percentage of cure, in cases where lateral sinus thrombosis arises, is high, but in the future it may be expected, with the early use of chemotherapy, that this complication will be progressively more rare. Apart from the Schwartze or other original operation there should be next to no need of any added major operative procedure and, consequently, a greatly lessened stay in hospital.

Meningitis is a fairly common complication of mastoiditis. Its early diagnosis is important.

Progress in the treatment of meningitis is so intimately dependent upon early diagnosis that I shall now discuss the sign upon which early diagnosis depends. The picture of meningitis I need not detail.

The most important sign in my opinion is early stiffness of the neck. You know how easily anyone, and especially a young child, is able to flex the neck, put the chin on the chest, and then move the chin laterally—i.e. rotation. The slightest restriction of extreme flexion and rotation is demonstrable by comparison with a normal patient, and is the most valuable sign.

In a paper on meningitis, T. B. Layton (1935) laid great stress on this early stiffness of the neck. In spite of views to the contrary, I think this sign is always present if it is looked for in the manner which he described.

On one occasion I was called to a fever hospital to see a nurse. Three days previously she had a pimple just inside her nose, and as she was going to a dance that evening she pricked it. When I saw her, she was lying on her back, her head propped up by pillows, with violent headache and a high temperature. I took the pillows away and tested her neck. She could bend her neck easily up to the angle of rest on the pillows, but beyond that it was rigid. Diagnosis—meningitis. The doctor in charge said “nonsense, she can flex her head easily,” and so she could up to the angle of rest. We did a lumbar puncture: the C.S.F. was very cloudy—she died in 24 hours. I mention this as one of the pitfalls in testing the neck for stiffness.

Twenty-five years ago, meningitis was a deadly complication. About 80% or more of the cases died, and although one's luck varied, the results were poor, or at any rate mixed, until the sulphonamides arrived. In 1929 I had three cases in succession who survived but this was just a flash in the pan.

My personal results improved after using the technique of T. B. Layton (1935), that is early operation to remove the focus of infection, with free removal of the

tegmen, keeping the wound open by means of stitching the flaps back, and flushing regularly with saline. As a modification, later I used hypertonic saline packs. Lumbar punctures were done daily, and sometimes twice daily. My figures improved to over 30% recovery with these methods. I also tried injecting the theca with various antiseptics, solganol and others, but it did not appear to affect the recovery rate.

In the early thirties, Neuman evolved an operation with a very wide removal of the tegmen tympani as far forward as the eustachian tube, elevation of the dura and exposure of the upper surface of the petrous, then wide removal of the tegmen antri. Ruttin (1934) using this method claims a 50% recovery. These were the best results published up to 1934. Sulphonamides increased the recovery rate greatly, up to 50%, and penicillin has improved it still further, until to-day the recovery rate is over 80% in uncomplicated cases.

TABLE I.—BENIGN FORMS OF OTOGENIC MENINGITIS (MYGIND, 1922)

Based upon the observation of 210 patients with meningitis of all forms, caused directly or indirectly by acute or chronic middle ear suppuration, over the past seventeen years.

Meningitis (uncomplicated)	Total	Recoveries	Percentage
„ plus sinusphlebitis	115	38	33.0
„ plus brain abscess*	42	16	38.1
„ plus subdural abscess	21	4	19.0
„ plus subdural abscess plus brain abscess	2	0	0.0
„ plus sinusphlebitis plus brain abscess	15	0	0.0
„ plus sinusphlebitis plus subdural abscess	6	0	0.0
„ plus sinusphlebitis plus brain abscess*	7	1	14.3
	210	59	

*Including encephalitis.

= 28% recovery.

These are the best, and by far the most complete results published in the *J.L.O.* up to 1922. 28% over-all recovery.

My personal results for seven years after 1922 show a 19.6% recovery. This is just less than 20% against Mygind's 28% all cases.

TABLE II.—TWENTY-ONE CASES OF OTOGENIC MENINGITIS SHOWING THE TIME-RELATION OF OPERATION ON THE EAR TO THE COURSE OF THE ILLNESS, THE PREVIOUS HISTORY, THE RESULT AND THE CAUSE OF DEATH (CAIRNS, 1946).

Operation	No. of cases	Previous otitis	Recovered	Died	Cause of death
Mastoidectomy before meningitis	3	2	2	1	Abscess
Mastoidectomy at height of meningitis	3	1 (? 2)	2	1	Heart failure and inhalation pneumonia
Myringotomy at height of meningitis	1	1	1	0	
Mastoidectomy during convalescence	2	1	2	0	
No operation	13	4	9	4	
	22		16	6	

= 72.72% recovery.

One patient (Case II) had two operations.

Previous otitis = a previous history of infection of the ear.

This paper was the result of experimental research by Professor Cairns and his team. As an experiment it is a remarkable tribute to the power of present-day chemotherapy. I should like to draw attention to one or two facts in this table, but not in a critical vein.

It is interesting to note that in those cases: (a) Operated on (9 in all) only 2 died—77.7% recovery; (b) not operated on (13 in all) 4 died—69% recovery.

This is in spite of the fact that in 6 of (a) no pre-operative chemotherapy had been carried out.

Professor Cairns states that in the 13 cases operation could not have altered the course of the disease. This statement is debatable. He postulates two questions: (a) Is the brain abscess produced concomitantly with the meningitis? (b) Is it produced later?

Nobody can answer these questions definitely, but, if it is later, and we know it often is by direct extension from the mastoid through the tegmen, then early mastoidectomy might have saved the two brain abscess cases, and even the acute cerebral oedema.

I have no knowledge, but I can quite appreciate the diffidence of aural surgeons advising operative interference during this experiment—evidently they were not consulted in some of the cases.

In this experiment it will be observed that brain abscess, even in the hands of a neurosurgeon, caused most of the deaths—3 out of 6.

TABLE III.—A SERIES OF 13 CASES OF MASTOIDITIS WITH MENINGITIS FROM 1.1.44 TO 1.9.47. 2 DEATHS IN 13—84.6% RECOVERY. DONALD WATSON, BRADFORD

Date	Name	C.S. fluid	Organism	Treatment	Findings
13.1.44	J. C. B.	Cells + (5)	Streptococcal	Sulph.	Mastoiditis and meningitis
10.4.44	H. B.	Cells + (6)	Small coagulum	Sulph.	Mastoiditis and brain abscess
19.5.44	L. J.	(1)	No growth	Sulph.	Mastoiditis and meningitis
9.1.45	G. O.	Cells ++ (2)	No growth	Sulph.	Mastoiditis and meningitis
18.4.45	A. P.	Cells + (3)	Pneumococci	Sulph. and pen. intrathecal	Mastoiditis and meningitis
18.9.45	V. N.	Cells ++ (5)	No growth	Sulph. and pen. intrathecal	Mastoiditis and meningitis
29.12.45	M. B.	Turbid (3)	Streptococcal	Sulph. and pen.	Mastoiditis and meningitis
7.1.46	R. P.	Turbid cells + (3)	Streptococcal	Sulph. and pen. intrathecal	Meningitis
6.2.46	J. B.	Cells + (3)	No growth	Sulph. and pen.	Mastoiditis and meningitis; lateral sinus thrombosis ligature of vein
12.2.46	G. B.	Cells ++ (1)	No growth	Sulph. and pen.	Mastoiditis and meningitis (died 14th)
4.9.46	W. S.	Turbid (2)	No growth	Pen.	Mastoiditis and meningitis (died 11th), oedema of lungs, duodenal case
23.12.46	R. C.	Cells + (8)	No growth	Pen.	Mastoiditis and meningitis
19.8.47	M. F.	Clear (2)	No growth	Sulph. and pen.	Mastoiditis and meningitis

The figures in brackets indicate the number of lumbar punctures performed. Sulphathiazole was used in every case.

This table emphasizes the value of chemotherapy, which was given in all cases before operation for about twelve hours, and continued after operation until the T. had remained normal for two days. The recovery rate of 84.6% compared with my earlier records up to 1927 of 20% recovery rate needs no comment. All the cases except one (7.1.46. R. P.) had mass mastoidectomy performed.

Labyrinthitis.—The subdivisions of this disease usually given in a textbook are somewhat bewildering.

The circumscribed type with the fistula sign is definite, as is the diffuse purulent type, but the serous types are not so definite and clinically do not matter—if left alone they recover. Lastly, there is the latent diffuse type—probably with a dead labyrinth.

As a complication of acute mastoiditis, I have seen only one case of diffuse purulent labyrinthitis with its severe symptoms, a small boy of 6. He had an extremely severe mastoid infection with labyrinthitis, lateral sinus thrombosis and meningitis. He died twenty-four hours after admission. I had performed a Schwartze operation in the meantime, but his was a fulminating generalized infection. At the post-mortem the saccus endolymphaticus was a bag of pus—the only case I have seen. I am aware that, through the years, recoveries of a few cases of acute diffuse labyrinthitis have been reported in the journals. This rare complication of mastoiditis—primary acute diffuse purulent labyrinthitis—is almost certainly a blood-borne infection as is primary pan-opthalmitis.

I shall return to serous labyrinthitis in acute mastoiditis. In the following remarks, I shall discuss two problems:

(1) The inadvisability of testing the labyrinth by caloric and rotation tests in cases of mastoiditis with labyrinthine symptoms, either acute or chronic.

(2) The relationship of labyrinthitis and meningitis. This problem appears to me to be more readily studied and understood in acute than in chronic mastoiditis.

The accepted views on labyrinthitis were clearly expressed by E. D. D. Davis (1928). He stated:

"The records of cases of meningitis which followed chronic suppuration reported by Logan-Turner, Fraser, Jenkins and myself have shown that the symptoms and signs of labyrinthitis were present in a very large proportion. Vertigo, tinnitus, nystagmus and a marked degree of deafness accompanied by headache and fever with an increase of cells in the cerebrospinal fluid call for a translabyrinthine drainage of the meninges without hesitation. There are certain signs of the spread of infection which forecast coming events. *Labyrinthitis is such a sign, and it requires careful investigation and prompt action as soon as it becomes apparent.*"

Tweedie (1934), who knew as much as anyone of his generation about the physiology of the labyrinth, supports the above view. In a paper published in 1934 he stated that in inflammatory lesions of the labyrinth—as in inflammation of any other organ—the normal responses to stimuli were upset, and all sorts of contradictory results obtained. In his 7-point summary of the tests, in point 6 he stated "that an attempt should still be made to assess the inference of spontaneous nystagmus in cases of acute otitis media". Previously he states that it is in these acute cases where we require assistance in assessing the amount of labyrinthitis that we shrink from applying the tests, and that generally we restrict the use of the labyrinth tests to chronic inflammatory cases of otitis media to determine whether or not the labyrinth is still functional.

I am of opinion that the above views are entirely wrong, and if carried into practice increase the danger to life in the treatment of labyrinthitis whether associated with acute or chronic mastoiditis. During the four years 1922–25 I carried out the usual cold caloric and rotation tests (Cold water (65° F., 17° C.) and the Bárány chair) in all cases of chronic mastoiditis. I operated on 3 cases with signs of labyrinthitis, and all 3 cases died of meningitis. During these years my colleague had no deaths. On careful investigation I found that the difference between his technique and mine was that he did not test any cases of labyrinthitis, whereas I did both caloric and rotation tests. I think it was the late Mr. Albert Gray who said that the labyrinthine capsule had great powers of defence and was capable of looking after itself in the presence of aural infection. As a result of these practical and theoretical considerations, I decided to stop testing the labyrinthine function, and wherever symptoms suggestive of labyrinthine upset occurred, to put the patient at rest, sand-bagging the head. During the twenty-one years that have passed since then, though I have had a number of cases of circumscribed labyrinthitis with the fistula sign, I have had no deaths from labyrinthitis in chronic mastoid disease.

It is my emphatic opinion that cases of mastoid disease in which labyrinthitis is suspected should be left at rest and that this complication will disappear in about three weeks. Several reasons may be put forward for regarding the widespread practice of testing the functions of the labyrinth in those cases as both useless and dangerous.

The labyrinth is endowed by Nature with strong defensive powers against infection. It is separated from the middle ear by a thin layer of bone—the stapes in the oval window, and the round window—and has to resist infection from a vast number of cases of middle-ear suppuration and mastoiditis annually. I have diagnosed about 6 cases of petrositis, but none complicated by labyrinthitis; cases of Gradenigo's syndrome without labyrinthitis; cases of herpes of the geniculate ganglion; all of which had vestibular upset, but all recovered. In chronic mastoiditis, I have had a number of cases of circumscribed labyrinthitis with the fistula sign. Since 1926 not

one has developed diffuse labyrinthitis. Surely all these points are evidence of its great resistance to infection.

The rarity of severe labyrinthine infection compared to the vast number of middle-ear infections bears witness to the efficiency of its defensive mechanism. Where it becomes mildly infected and Nature has succeeded in walling off the infection it is surely dangerous to subject the patient to a series of tests which, I believe, are well calculated to break down the natural barriers and produce diffuse labyrinthitis, just as perforation of an acutely inflamed appendix sets up dangerous peritonitis. Tests of functional activity suitable in physiological conditions may be fraught with danger in pathological conditions and should be avoided. If active surgical treatment is indicated for the mastoiditis it should be carried out, but the labyrinthine upset should be left undisturbed and allowed to settle.

There is an analogy between the eye and the ear. Both are developed from the ectoderm. Primary acute pan-ophthalmitis is rare. The lesser degrees of inflammation interfering with function are more common, similar to cases of serous labyrinthitis which, if left alone, and rested will recover.

To conclude this portion of my paper, I believe that the use of these physiological tests on the labyrinth is the direct cause of the many cases of diffuse purulent labyrinthitis in chronic aural suppuration and the reason of the many translabyrinthine operations. These operations, with their fatalities, are a blot on our escutcheon.

I wish now to return to serous labyrinthitis in acute mastoiditis and to discuss the second problem, i.e. the relationship between labyrinthitis and meningitis.

Apart from the single case of acute purulent labyrinthitis already mentioned, I have seen a number of cases of acute mastoiditis with labyrinthine symptoms. One of these cases, about 1933, caused me much worry, and also gave me the key to this problem. She had an acute mastoiditis with very marked signs of labyrinthitis plus meningitis and a temperature of 104° F. Her symptoms subsided after the Schwartze operation had been performed. This wound was left open and treated according to Layton's technique. Lumbar puncture showed increased pressure in the C.S.F. with some increase of cells but no organisms. This patient not merely recovered but she regained her hearing. She could not have had a purulent labyrinthitis: it had been of a serous type, yet her labyrinthine symptoms had been so extreme that I diagnosed her as a fulminating case of acute diffuse purulent labyrinthitis plus meningitis, and gave her father, who was a doctor, a fatal prognosis.

In this case there were marked symptoms of labyrinthitis plus meningitis. These should be regarded as two manifestations or complications of the parent acute otitis media—twins if you like, but not Siamese twins—separate entities.

In many clinics of the Continent and elsewhere, *if such a case of labyrinthitis plus meningitis with an increased cell count had occurred, labyrinthine drainage would have been done at once*, on the supposition that the meningitis develops from the labyrinthitis and this, I think, is wrong. Nearly all are simply cases of serous labyrinthine upset—the meningitis is the danger. It must be treated and has nothing whatsoever to do with the labyrinthine condition. The labyrinthitis heretofore has been regarded as the danger causing the meningitis.

There is one other condition that *does* occur, that is induced purulent diffuse labyrinthitis induced by operative procedure or injury, and this applies equally to the eye. Labyrinthitis induced by operation may occur once in every surgeon's life, but it should be only once, and to-day, with chemotherapy, the patient should live. When induced purulent diffuse labyrinthitis is produced, it infects the meninges. This sequence has frequently occurred, and is responsible for most of the work and written papers on labyrinthitis in the past. There has been no progress in any published material on labyrinthitis.

SUMMARY

(1) *Infection*.—The labyrinth is very resistant to infection, and diffuse purulent labyrinthitis is rare and is, or should be, almost entirely a primary disease.

(2) *Tests*.—(a) Diffuse purulent labyrinthitis, following labyrinthine tests, I regard as induced.

(b) The practice of testing the labyrinth is due to a confusion of thought. Physiological tests of function have been used on the labyrinth when it is in a pathological state. They are not clinical tests, and should be discontinued.

(3) *Relationship of labyrinthitis to meningitis*.—(a) Even when labyrinthine symptoms are very severe, they may not be due to a purulent infection of the labyrinth. They are simply a labyrinthine upset—"serous labyrinthitis" if you like the term.

(b) This labyrinthine disorder will recover without any interference with the labyrinth, provided, of course, the patient recovers from the original mastoiditis and its other complications.

(c) Meningitis is not as a rule caused by labyrinthitis as many observers think. It is always a primary complication of mastoiditis.

(d) Labyrinthine upset may be associated with meningitis, but the two conditions are entirely distinct. This is the fundamental point in the understanding of this problem.

The complication of brain abscess has not been included. It is a difficult problem. There has been marked progress in its prevention since its parent, the acute mastoid, is becoming more scarce because of chemotherapy.

Mr. E. D. D. Davis said that it was most important to decide when to operate on a case of acute mastoiditis. The operation should be delayed if possible until the mastoiditis was localized and suppuration was present. If the mastoid were opened too soon, healing was prolonged, and the inflammatory condition appeared to spread. On the other hand an abscess healed rapidly. If all the air cells were opened in the simple complete mastoid operation a drainage tube for forty-eight hours only was all that was necessary. It was the unopened suppurating air cell which caused trouble and not the lack of drainage. Packing the wound with gauze led to a surface slough and secondary sepsis and must be avoided, a drainage tube was far better.

When meningitis was threatened the wound was left open but not packed. Rigidity or slight stiffness of the neck was a too late sign. Very few cases of meningitis with rigidity of the neck recovered. The rigidity was caused by a collection of purulent fluid in the basal cisterna and around the crura cerebri. The examination of the cerebrospinal fluid was the only way to make an early diagnosis. Cases of meningitis arising from a blood-borne infection died very rapidly as in the case the President had mentioned.

In 1922 it was agreed that an operation on the labyrinth for labyrinthitis should not be done before the labyrinthitis was localized. A threatened or established meningitis demanded operation.

Lund of Copenhagen and others relied on the examination of the cerebrospinal fluid. If the count increased it was an indication for operation. A large number of labyrinth operations had been done because of the fear of meningitis.

Children and young adults were more susceptible to meningitis than old people. The unexplained severe headache with a rise of temperature and pulse, the cellular mastoid pouring serous fluid with deep-seated pus in the cells behind the facial nerve, the mastoid following scarlet fever and measles

all pointed to the possibility of meningitis. Treatment by sulphonamides and penicillin had improved the prognosis of meningitis.

Mr. T. M. Boyle made a plea for the use of heparin in a small number of cases of lateral sinus thrombosis. He cited the case of a girl aged 15 who had the lateral sinus drained and continued to have rigors for about a week afterwards. She was having large doses of penicillin and sulphonamides. Then a general surgeon put her on heparin, and from that day she made a rapid recovery. He would not say that all cases should have heparin, but those cases not responding to treatment. In another small group of cases of mastoiditis there were resistant organisms, *B. pyocyaneus* being one of the offenders, and here he thought phenoxetol, a proprietary preparation, was of great value. He recalled a case which had had the mastoid opened about ten years ago, and later developed a recurrence: an attack of mastoiditis with a green discharge. It dried up but recurred on several occasions. The mastoid was opened and the drainage tube inserted and phenoxetol applied in the cavity. Within three days the discharge from the external meatus was sterile, and within six days the middle ear was dry.

Mr. W. H. Bradbeer said, with regard to latent labyrinthitis, that two patients in whom he suspected that the labyrinth was dead both developed meningitis following operation. One was a mild case and recovered. In the other a very severe meningitis developed, and eventually a cerebellar abscess, but this case also recovered after opening the labyrinth and draining the abscess. If one was doing a radical mastoid operation with a dead labyrinth he had come to the conclusion that one should open the labyrinth as well, but after what the President had told them he was uncertain on that point. He thought they would still see chronic ears, and one came across children in school clinics with chronic otorrhœa and with an attic perforation.

Mr. F. McGuckin said he believed a cerebral abscess might arise at any stage of an otitis because of the possibility that a localized infection in a perivascular space might act as a preformed path. On the question of labyrinthitis he agreed almost unreservedly with the President's plea, in so far as the complication was related to acute otitis.

Mr. F. W. Watkyn-Thomas said that a danger in using heparin was that the clotting time was altered for a considerable time afterwards, which might give trouble should further surgery be needed. The justification for the use of heparin in sinus thrombosis would be to make sure that the antibiotics came into contact with the organism; an organism in the clot was safe from anything in the way of penicillin or sulphonamide treatment.

On the question of translabyrinthine drainage, since the use of sulphonamides he had only seen two cases of meningitis which were undoubtedly due to labyrinthine infection—at any rate they had certainly followed upon a labyrinthitis. In these two cases he refrained from translabyrinthine drainage because he felt that, if the cerebro-spinal fluid was released, it would be more difficult to keep up the requisite sulphonamide concentration. Both patients recovered. The translabyrinthine operation had been the greatest advance in treatment in its day, but now it would rarely, if ever, be necessary.

Mr. Ogilvy Reid referred to the rarity of such a complication as facial paralysis in acute mastoiditis or acute otitis media. He had in mind one or two recent cases which illustrated the difficulties which chemotherapy had introduced in the treatment of mastoid conditions and the way in which the picture was obscured. One case had had massive doses of penicillin and was apparently doing very well when a facial paralysis developed. He operated on the case and though he found no lesion relating to the facial nerve yet the facial paralysis began to recover after the operation.

Mr. R. R. Simpson asked what would be the President's attitude in the case of the labyrinth in the presence of otitis media with fistula signs? He himself did a radical mastoidectomy in such a case without interfering with the labyrinth at all, and so far he had never regretted it.

Mr. J. H. Otty felt sure that an adequate dosage was the essential in the use of the sulphonamides or penicillin, but it was equally important to tighten up the criteria of cure. These patients should not be let out of hospital unless the surgeon was satisfied, not only that the ear was dry but that the tympanic membrane had returned to normal and the hearing had been restored.

Mr. L. Graham Brown said that as a senior he felt that he had had a considerable experience of these cases during the past quarter of a century. The young practitioner only saw the question from his own recent experience, and naturally was a little perturbed as to what the treatment really ought to be. The time had now come when chemotherapy had taken a large part in the treatment of these affections. He wished to say with regard to chemotherapy that he used it only as an adjunct to

surgery. They were all aware that its application in the early stages of acute inflammation of the middle ear might be successful in relieving the condition, but also they knew the dangerous effects which might be brought about if it was used at a time when pus was formed in the middle ear or the mastoid bone or in the further complications of the disease. They were aware of the fatalities which occurred. Perhaps the mastoid operation would be followed by almost complete resolution, and then, some weeks afterwards, a brain abscess or meningitis occurred and the patient often died.

He had not operated on a case of labyrinthitis for many years—perhaps fifteen years. Cases in which there were signs of labyrinthine irritation in chronic disease of the mastoid, which flared up, he had dealt with by performing a radical mastoid at the opportune time, providing there was no evidence of the disease spreading to the meninges. Such cases had invariably got well. In view of the statements that these cases were rapidly diminishing, it was strange that Mr. Simson Hall should have seen recently several cases of lateral sinus thrombosis. He himself had not seen one for two or three years, but, curiously enough, he had three cases of meningitis, and these were cases of chronic mastoiditis, all of which, after removal of the focus in the mastoid—going no further, and putting them on chemotherapy—had recovered. The most important thing was to learn how and when to use chemotherapy.

Mr. Terence Cawthorne said that the high light of the President's Address was that he had had the courage years ago not to treat the labyrinth surgically in the early stages of an infection. Most of them had come to realize, now that they had recourse to chemotherapy and biotherapy, that early surgical treatment was wrong. He agreed with Mr. Layton who had suggested that chemotherapy should precede surgery even in chronic conditions where there was an acute flare-up.

Mr. H. S. Sharp said that in acute middle-ear disease he never gave chemotherapy unless he had first obtained drainage from the ear. Such cases were followed up very carefully by means of X-rays, and in adults, in addition to X-rays, by tests for deafness.

The President (Mr. Watson), in a brief reply, said that if there was any surgery to be done it must be done and done early, but on cases that had been on penicillin or sulphathiazole for three or four weeks there was no harm in operating if there was any doubt. Mr. Boyle had spoken of cases in which sulphathiazole and penicillin were given at the same time. That was an interesting point and one for discussion in the Section. He had seen two cases of meningitis in patients who had had too large doses of penicillin and sulphathiazole. The temperatures did not drop and he could not understand it. In one of the cases he stopped penicillin and the temperature dropped immediately, nothing else happened. In the other case he stopped sulphathiazole, with the same result. Some of these patients were "killed by kindness". Too much in the way of antibiotics could be given. Whether heparin counteracted the effects he could not say.

There had been a great deal of confusion about the chronic mastoid. People talked about labyrinthitis after they had been, he was sure, testing the cases. He himself would not have anything to do with testing, and if anyone talked about labyrinthitis after having done caloric, rotation or electrical testing he thought it a sequel. The plea he would put forward was to stop physiological tests. He drew an analogy from the heart. There was a tolerance test for the heart by which one observed the heart's function. This was carried out on a normal or near-normal heart. Would a clinician test a heart with valvular disease by means of these tolerance tests? Would he test a patient with a temperature of 102° F. whom he thought was developing endocarditis by asking him to run upstairs and down again? Of course he would not, but it was something like this that they had been doing in otology.

The History of Cholera in Great Britain

By E. ASHWORTH UNDERWOOD, M.A., B.Sc., M.D., D.P.H., F.I.S.

ALTHOUGH Asiatic cholera did not visit the shores of this island until 1831, it had quite a respectable history long before that date. Macnamara [1]—an authority on the history of cholera in the East—thought that the disease may have existed in India in 400 B.C., and there are records of outbreaks in the fifteenth century. The devastating epidemic which prevailed in Lower Bengal in 1817 was the occasion of a number of short treatises on the subject by Europeans. Several of these were in the form of Latin theses presented to the Universities of Glasgow and Edinburgh [2]. Cholera reached Europe in 1829, and during 1830 and 1831 it was widespread in the countries of Central Europe. In Great Britain generally much interest was caused, and many fears aroused, by the continued existence in Europe of a disease which had until then been regarded as purely Asiatic. Preventive measures included the formation of a Central Board of Health with Sir Henry Hallford as President, and also of many local Boards of Health in different parts of the country.

About this time nearly all observers were much concerned about the indigenous "cholera" of Britain. It was known as "cholera nostras" and by various other names, and in certain features it did resemble Asiatic cholera. How were medical men to decide whether the true cholera had arrived, or whether they were still dealing with severe cases of cholera nostras? In order to settle this point the Central Board arranged for consultations to be given by medical men who had had experience of Asiatic cholera in the East. But the Eastern disease had a way of its own of settling the question, and when it did arrive the issue was never long in doubt.

The epidemic of 1831–32.—The first death from true Asiatic cholera in this country occurred in Sunderland on October 20, 1831. After a slight lull the disease took a heavy toll during the next few months, so that by January 9, 1832, 215 deaths from cholera alone had occurred in Sunderland. Cholera next appeared at Newcastle on December 7, 1831, and there it ran most of its course during the next few months. It did not finally exhaust itself until the summer, by which time there had been over 1,330 cases and 801 deaths. Gateshead and other Tyneside towns were attacked about Christmas or the New Year. Almost contemporaneously cholera appeared in Haddington. The first case occurred on December 17, and the next on the 25th. By February 23 there had been 125 cases with 54 deaths [3]. A little later the Tranent area was affected. The town of Tranent itself, with a population of 1,631 persons, had 204 cases and 64 deaths; and the villages of Cockenzie and Port Seton, and the town of Prestonpans, with a total population of 2,717 persons, had 195 cases and 36 deaths [4]. The small town of Musselburgh suffered a devastating attack, and between January 18 and February 22 there were over 400 cases and 202 deaths. The next areas to suffer the dire effects of the new disease were the large cities and the industrial centres—Edinburgh at the end of January, and Glasgow during the second week of February. In each the disease seemed to be exhausting itself about the beginning of the summer, but in July and August it sprang to life again in an even more violent form. In Glasgow alone there were 3,166 deaths—the highest mortality figures in the country, apart from London.

The epidemic in England fell much later than in Scotland, and really occurred in the summer and autumn. London was an exception, since the disease started there about February 14, and dragged on until the end of the year. The first important provincial city to be attacked was Hull. This was during the first week of April. The disease had broken out at Liverpool by the end of that month, and between then and the middle of July severe outbreaks had commenced in Manchester, Salford, Leeds, Plymouth, Sheffield, Nottingham, Bristol and Exeter. In a previous communication [5] I gave a full account, with a statistical discussion, of the epidemic as it affected the centres of population in Yorkshire. Hull and Goole were considered by the Central Board of Health as infected from April 6, but the first authentic cholera death in this area probably occurred on April 13. Alderson [6] described this outbreak well, and from his account it would appear that the disease did not really make itself felt until June, by which time it was epidemic throughout Yorkshire. Most deaths occurred at Leeds (702), Sheffield (402), Hull (300), and York (185). The writings dealing with the Sheffield outbreak were collected in 1921 by Stokes [7]. In Lancashire the

greatest number of deaths occurred in Liverpool (1,523), Manchester (706), Salford (216), and Warrington (168): The Manchester outbreak was well described by Gaultier [8].

From the numerous writings which appeared during these early months of 1832 it is evident that cholera was regarded as a visitation of Divine Providence on the vicious and an unfortunate catastrophe in the lives of the poor [9]. Most of the early reports emphasize the fact that the disease attacked those who were addicted to spirits, and that it was confined to the shacks and hovels of the new industrial districts. Doctors and nurses generally escaped infection, and the better-class districts were not affected.

Later in the year opinions began to change on these points. At any rate, nearly all the reports emphasize the frequency of unpaved streets and yards in the cholera areas; the absence of satisfactory arrangements for the removal of filth and the cleansing of privies and cesspools; and the necessity for lime-washing houses and adding nutritious articles to the diet [10]. There were some who denied the earlier opinions regarding the type of persons who were most readily infected. For example, Lawrie [11], in his essay on the cholera in Sunderland, Newcastle and Gateshead, says that it is not true that the poor and the dissipated are its only victims. He denies also that fear can predispose to the disease. "I do not believe", he says, "that fear ever gave a man Cholera or ever will. To the production of Cholera a regular chain of causes and effects is as necessary as to poisoning by prussic acid. The inhabitants of Gateshead fell asleep on the 25th December, in perfect security and devoid of panic, but before the sun rose on the 26th, fifty-five individuals had been seized, thirty-two of whom were destined not to see it set. For several days subsequent to the 27th, the panic of the inhabitants was greater than I have ever witnessed under any pestilence, while the new cases *decreased*, and on the 30th were as low as twenty". This passage is reminiscent of Boccaccio's celebrated description of the plague in Florence.

Of all the outbreaks during this momentous year, three stand out because of the havoc which they produced, or because of the fact that they have been well described. The Exeter outbreak was fully written up by Shapter seventeen years after its occurrence [12]. Thomas S. Shapter, incidentally, was a well-known Exeter physician. Born in Gibraltar in 1809, he died in London in 1902 at the age of 93. He was a skilled draughtsman, and he had other non-professional interests [13]. Shapter described very well the difficulties which confronted the Local Board of Health, and the deplorable results of the jealousy which existed between it and the Corporation of the Poor. In 1933 I said that I regarded this book as "one of the best descriptions extant of an historical epidemic" [14], and in the following year Mr. R. H. Mottram quoted freely from Shapter's work in opening his chapter on "Town Life and London" in an important collaborative volume [15]. The population of Exeter at that time was 28,242 persons, and there were at least 1,135 cholera cases with 345 deaths. Perhaps the most important part of Shapter's work deals with the various administrative measures which were taken to check the disease, and the attempts which were made to improve the sanitary conditions of the town. The disease first appeared there on July 18, 1832. A local Board of Health had been formed in the City on November 1, 1831, so that the community was as much prepared as it could be at that time. There were great difficulties regarding the provision of an efficient water supply. Until then water for drinking purposes had been obtained from private wells, a few public pumps, the waterworks, and the ancient conduit—the history of which extended back to 1221. By the efforts of Mr. James Golsworthy, the proprietor of the waterworks, fairly satisfactory arrangements were later effected. Shapter gives a very interesting description of the method which was adopted to cleanse the streets. The water was turned on at the fire-plugs, and the stream was dammed in the gutter with coils of straw. Men with wooden shovels then "threw" the water over the road surface. The mean mortality during this epidemic in Exeter was 33%.

In point of time the next important outbreak was that at Bilston in Staffordshire. In 1832 this town had close on 15,000 inhabitants—most of them employed in the furnaces and the mines. A case of cholera occurred on August 3, and within a week there were 150 cases and 36 deaths. The whole outbreak ran its course in seven weeks. The number of cases officially returned to the Central Board of Health was 3,568, and there were 742 deaths. The Rev. W. Leigh, the Incumbent of Bilston, chronicled this outbreak in the following year. His simple record of the events conveys—perhaps more convincingly than impassioned language would have done—the dreadful ordeal of those who lived daily with the dead and themselves feared that they would be the next victims. Writing of August 23 he says: "The condition of Bilston had now become frightful. The pestilence was literally sweeping everything before it, neither age, nor sex, nor station escaping. . . . To describe the consternation of the people is impossible. Manufactories and workshops were closed; business completely at a stand; women seen in a state of distraction running in all directions for medical help for their dying husbands, husbands for their wives, and children for their parents; the hearse conveying the dead to the grave, without intermission either by night or day; those inhabitants who possessed the means quitting their homes, and flying for safety to some

purer atmosphere; those who remained, seeing nothing before them but disease and death [16].” The Rev. Leigh deserves to be remembered and mentioned in the same breath as the Rev. William Mompesson, the plague hero of Eyam in 1665.

The third outbreak to which I shall briefly refer was that at Dumfries [17]. A Board of Health was constituted in that town on March 15, 1832, and active efforts were made to improve the nutrition of the inhabitants and to abate sanitary nuisances. As in Exeter, the domestic and drinking water was provided from the near-by river, and it was sold from door to door by the four water-carriers. Cholera broke out in the town on September 15, 1832, but during the next ten days cases and deaths were not numerous. On the 25th, however, there were 14 new cases and 9 deaths. But the full force of the infection was now to fall on the town. In the succeeding period of six weeks 837 cases were reported officially, and 418 deaths occurred. In the adjacent burgh of Maxwelltown there were 237 cases and 125 deaths. In the combined urban area it is probable that there were at least 630 deaths during these six weeks. In a description of the outbreak it is said that “shops for general business shut at noonday; publicans warned to close their stores at dusk, that the vicious might be hampered in their evil propensities; every vehicle employed in removing family after family to the country; the public schools dismissed; St. Michael’s vacated from the dread of cholera graves, and Divine Service performed in the Courthouse; trade suspended, workshops depopulated, and industrious traders gathered into knots, discussing the fearful extent of the pestilence; many requiring medical aid, and partly from the force of terror alone; every countenance shaded with grief, and a whole community the picture of despair” [18].

We have several firsthand accounts of this outbreak, mainly written by Dr. Archibald Blacklock and Dr. James Grieve, who were in practice in the town in 1832, and who were responsible for the treatment of patients in the cholera hospital. Unfortunately, these letters all date from the years 1848–49 and 1854, and so were written long after the events described. In 1848 Grieve [19] described a peculiar tingling sensation, exactly similar to a slight galvanic shock, which was felt on applying the hand to the skin of a person in the collapsed stage of cholera. Much ink was spilt in endeavours by various persons to establish priority for this observation. More important, Grieve set out in some detail his reasons for believing that cholera is not contagious, and he considered that the diffusion could only be satisfactorily accounted for by admitting the influence of “epidemic causes”. In February 1854 Grieve [20] reverted to the question in a communication dealing with remarks made by W. T. Gairdner in a discussion. From Gairdner’s reply it is evident that there was in Dumfries a strong opinion against the contagiousness of cholera, and that Grieve had been an advocate of this opinion [21]. The old records were then gone over carefully by Blacklock [22] who says that although he had previously felt that, where cholera prevailed, it was the locality and not the sick which had to be feared, the records of the first eight days of the 1832 outbreak had changed his views. He says that “the progress of the disease during the first eight days was, to use the favourite term of Sir Gilbert Blane, more like one communicable by emanations from the human body than one entirely owing to atmospheric influence, or any other influence with which we are acquainted”.

It is unnecessary to refer to the further correspondence which is of some interest from an epidemiological standpoint. During this outbreak four medical men out of 21 practising in the town were attacked, and two of them died [20]. There was apparently no discrimination between the houses of the rich and those of the poor. It is also interesting to read the account of an eyewitness, who was impressed by a dense mass of cloud which hung over the town “like a vast funeral pall”. The verbal picture which he paints is very reminiscent of the plague scenes depicted by some of the great artists: “A dense black canopy enveloped the whole skyey amphitheatre as far as the eye could reach, fringed by a narrow ray of pinky light along the horizon, and the sun rarely shedding a ray upon the towns in which death was so busy” [23].

During the period under discussion the question of the contagiousness of cholera continued to be hotly debated. By “contagion” the idea of actual contact was of course implied. Moir [24] in his important book supported the contagious nature of the disease, but he obviously did not appreciate that the infection does not pass direct. Molison [25] in his account of the cholera at Newcastle held that there are no grounds for believing that the disease is contagious, and as one fact in support of this view he states that he has often sat for half an hour on a patient’s bed, and that on one occasion he had wounded himself with a lancet while bleeding a cholera patient. The problem was often approached in a materialistic spirit. For example, Lizars [26] says: “I consider the pernicious doctrine of contagion has let loose upon the public mind one of the strongest auxiliaries to the propagation of the disease, viz. fear. This is well known, on ordinary occasions, to produce the premonitory symptoms of Cholera, or diarrhœa. The doctrine of contagion hardens the heart—destroys the finer and more amiable feelings of our nature; the kindly affection of

the father for his family is blunted or destroyed; the still stronger link of nature between the mother and her offspring is broken, and she looks on her innocent children as sources of danger. . . . The minds of the vicious are lulled into false security."

During the year 1831 cholera caused the deaths of 21,800 persons in England and Wales, and 9,600 in Scotland. There was a recrudescence in London in 1833, when the metropolis had 1,454 deaths, and also a few scattered minor outbreaks in other parts of the country. But for all practical purposes cholera had burnt itself out, and was not to be seen again in this country until 1848. In Table I are set out the deaths which occurred in the most

*Tables I and II have been compiled from various sources. In the case of Table II the data are taken especially from the Registrar-General's reports on cholera. Owing to the frequent occurrence of one or two cholera deaths in an area at intervals of some months before the actual start of the epidemic, the commencing date has generally been taken as that period when initial cases were closely succeeded by others. The difficulty in the diagnosis of sporadic cases seems to warrant this selection, but in any case there must be great difficulty in fixing the commencing date of such epidemics.

important cholera centres in 1832. I have arranged the data—compiled from various sources—chronologically, so as to show the spread of the disease through the country.

The epidemic of 1848-49.—The disease seems to have been conveyed from Hamburg, and it broke out in the Edinburgh district in the beginning of October. In the capital itself there were 448 deaths. On November 11 the disease reached Glasgow, and before it died out it caused 3,800 deaths [27]. The industrial towns of Lanarkshire and Ayrshire were also affected, and Dumfries had an outbreak which was almost as bad as that of 1832. In Dumfries the outbreak started on November 16, and continued until the first week of January 1849. It caused 317 deaths, together with 114 in the adjoining town of Maxwelltown [28]. The combined population of the two towns was then 14,000. Scotland was completely clear of cholera before the disease had obtained a foothold in England. Although there had been a comparatively small number of deaths in London during the autumn of 1848 and the first six months of 1849, it was in July, August and September that the disease really became epidemic in the metropolis. The peak month was September, when there were 6,644 deaths. Other towns which were heavily attacked during the autumn months were Plymouth (830) and Portsmouth (568). Most of the Lancashire cotton towns escaped lightly.

Although the 1832 epidemic caused more fear and appealed more to the popular imagination, the outbreak of 1849 was the most severe that this country has suffered. In England and Wales it caused 53,292 deaths. In Table II I set out data for 1848-49

*See footnote to Table I.

similar to those given in Table I. This table brings out the differences between the 1848-49 epidemic and that of 1832. The disease commenced in many different areas almost simultaneously, and, although there had been small numbers of cases in many areas in the early months of 1849, the brunt of the epidemic was borne by most areas in the summer and autumn months.

The epidemic of 1853-54.—This epidemic began with a fatal case in Newcastle on August 30, 1853. The incidence mounted rapidly, and by November 4 there were 1,533 deaths, together with a further 433 deaths in Gateshead. In the following year London had 10,738 deaths; Liverpool (1,084), Dudley (256), and West Ham (124) were also fairly heavily affected, and the small town of Wisbech had 176 deaths. In England and Wales as a whole there were 20,097 deaths in 1854.

The later outbreaks.—During the autumn of 1865 cholera—imported by a new route, from Arabia through Egypt—caused 35 deaths in Southampton. It then appeared at Weymouth, Portland, and Dorchester. Between September 28 and October 31 a small

outbreak with 9 deaths occurred at Theydon Bois in Epping Forest. This outbreak was investigated by Radcliffe, and was shown to have been due to the contents of a faulty cesspool leaking into a well [29]. 1866 was very definitely a cholera year. According to Simon [30] the first case appears to have occurred at Bristol on April 28, and by May 15 cholera was reported in the Mersey centres. The largest number of deaths reported was in London (5,596), and Creighton notes that in the metropolis the disease in 1866 left its old principal seats—Southwark and the parishes on the south of the Thames—and became localized to the East End. In the provinces Liverpool suffered most heavily with 2,122 deaths, and other towns which were relatively badly affected were Swansea, Merthyr Tydfil, Chester and Portsmouth. Although there were few large outbreaks apart from these, cholera was so widespread that it caused 14,378 deaths in England and Wales as a whole [31]. In Scotland there were 1,170 deaths, the places chiefly affected being Edinburgh (154), Dundee (105), Aberdeen (62) and Glasgow (53). A few cholera deaths took place in this country in 1873.

In 1893 there occurred the beginning of what might have been a serious epidemic. In the summer of the previous year the disease was raging in Hamburg, and it will be remembered that while both Hamburg and Altona used water from the River Elbe for drinking purposes, in the case of Altona the water was filtered while in the case of Hamburg no such precaution was taken. Altona escaped the infection completely. During this outbreak, in the period between August 25 and October 18, 1892, 35 cases of cholera reached the shores of Britain, but no residents were affected [32]. In the summer of 1893 the disease was imported again—to the Tyneside ports on June 25, and to Cardiff on July 18 and London on July 20. About the middle of July there was an excess of fatal diarrhœa at Grimsby (Lincs), and cases of true cholera probably occurred from the beginning of August. On August 24 the disease reached Hull, and on September 5, the first fatal case occurred in Rotherham. On September 7 a woman cleaner in the House of Commons had a fatal attack. Grimsby had the greatest number of deaths, 35. Next in order came Hull 12, Ashbourne (Derby) 9, and Cleethorpes 7. Exclusive of ship-borne cases, the total attacks from true cholera in England and Wales in 1893 was 287, and there were 135 deaths. The fatality rate was given by Thorne Thorne—the chief medical officer of the Local Government Board—as 47% [33]. This was the last occasion on which cholera gained a footing in this island.

John Snow and the cause of cholera.—The main interest of the outbreaks of 1849 and of 1854 centred round the mode of spread of cholera. I have already indicated that even as late as 1854 there was widespread disagreement on this question; although many felt that cholera was contagious, no one had succeeded in bringing forward evidence which could not be apparently shot to pieces by the other side. In 1832 John Parkin [34] had suggested that the cause of cholera is a noxious matter or poison which is generated in the earth, and that this finds its way into springs. Parkin also suggested that the water from such springs should be filtered through charcoal before use.

Such was the position in 1849, when John Snow first published a work on this subject. He was then a famous anesthetist, but unknown in the realm of epidemiology, although he had been interested for some time in the problem of cholera. His essay *On the Mode of Communication of Cholera* [35], a pamphlet of thirty-one pages, was published in 1849. He published later articles in the *Medical Times* (1851) and in the *Medical Times and Gazette* (1852). In 1852 he chose the title "On Continuous Molecular Changes" for his oration at the eightieth anniversary of the Medical Society of London. In 1854 Snow seized the opportunity for testing his theories during the occurrence of the Broad Street, St. James's, outbreak in London, and he further conducted a very extensive investigation into the incidence of cholera in the areas supplied by certain London water companies. In the following year he published a very much enlarged edition—now of 162 pages—of his essay [36].

Snow is beginning to receive the attention which he certainly deserves as one of the founders of epidemiology. In this short paper it is not possible to deal fully with his work, but as most of the accounts of his writings concentrate on the second edition of his essay, I propose to say something of Snow's earlier views, as found in his essay of 1849.

Snow begins by asserting his belief in the fact that cholera is propagated by human intercourse. He then goes on to argue that in cholera the alimentary canal is first affected, and he rejects the theory of effluvia, and that of poisoning of the blood in the first instance. A little later appears the illuminating sentence: "The excretions of the sick at once suggest themselves as containing material which, being accidentally swallowed, might attach itself to the mucous membrane of the small intestine, and there multiply itself by the appropriation of surrounding matter, in virtue of molecular changes going on within it, or capable of going on, as soon as it is placed in congenial circumstances." He gives as an analogy the introduction of the ova of intestinal worms into the body; and though the prevailing ignorance of the life-cycle of these parasites made the analogy inaccurate, it was nevertheless in some ways

striking. Snow then suggests that cholera may be widely disseminated by the emptying of sewers into the drinking water of the community, and he gives examples of cholera areas—such as Dumfries, Glasgow, and certain parts of London—in which these conditions existed. He proceeds to build up his case with examples of localized outbreaks in which it could be shown that the drinking water had become polluted with sewage. Then follows a type of argument which he was to develop much more fully in the second edition of his work. Snow pointed out that, of the five districts into which London could be divided, only the south

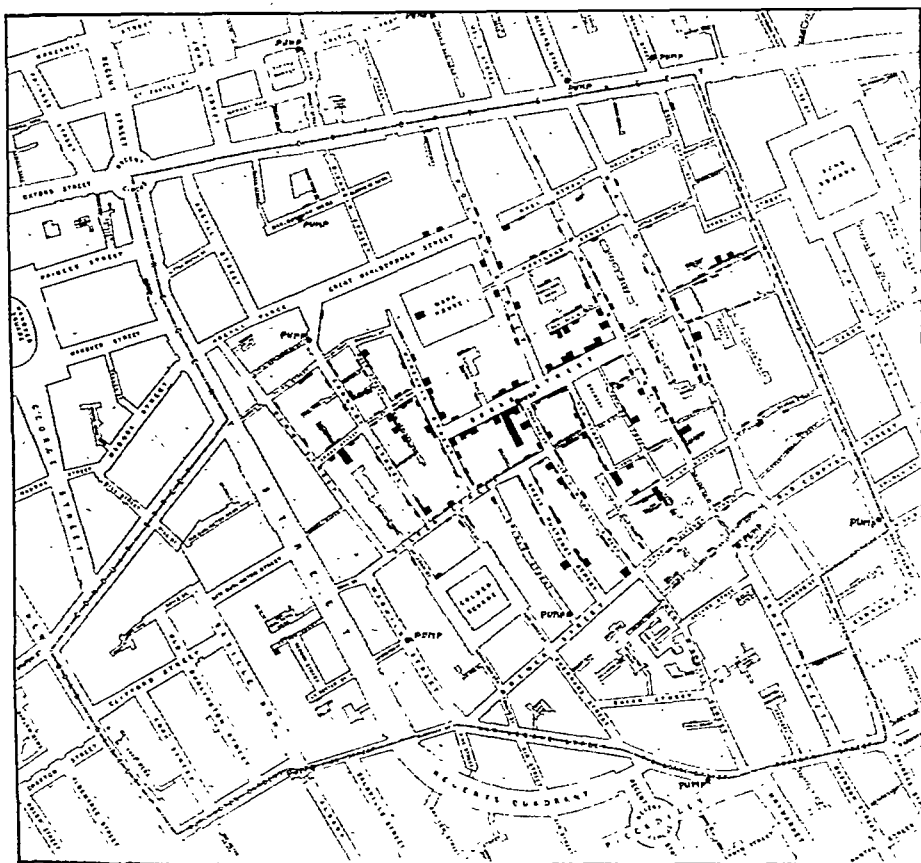

FIG. 1.—Snow's map showing the distribution of the deaths from cholera in the Broad Street (Golden Square) area of London, 1854 (from John Snow, *On Cholera*, London, 1855). The scale of the original map was 30 inches to a mile, and reduction is approximately to one-third.

district was supplied with water taken from the Thames at places where the river was much polluted by sewage. All the other districts obtained their water from points farther upstream, or from the New River or the River Lea. The Chelsea area was an exception. Though it took its water from the Thames only one or two miles above Vauxhall, it was at great pains to filter the water carefully. But the number of cholera deaths in a certain period in the south district—viz. 4,001—was more than that in all the other districts combined. He also makes the significant statement that, when the water had been contaminated, the possibility of the "materia morbi of cholera" being communicated to the inhabitants depended "on whether the water were kept in the reservoirs till this materia morbi settled down or was destroyed; or whether it could be separated by the filtration through gravel and sand, which the water is stated to undergo". Finally, there follows a brilliant anticipation of the germ theory of cholera, which should have served as a beacon to others: "As far as can be judged from analogy", he says, "the poison consists probably of organized particles, extremely small no doubt, but not capable of indefinite division, so long as they retain their properties." Snow summarizes in a few words the preventive measures which

are necessary. Attendants on the sick must wash their hands frequently; water which may contain sewage should not be used for drinking or cooking; or alternatively the water should be filtered or boiled before use. The south and east districts of the metropolis must have a sewage-free water supply.

Snow's second edition of 1855 was really an extension and confirmation of these arguments—but what a confirmation! The episode of the Broad Street Pump is known to many as a name, but only those who have read Snow's text will appreciate the force of the argument. It should be noted that his preface is dated "11 December, 1854", a matter of weeks after the conclusion of the outbreak. The centre of the "cholera field" was the pump in Broad Street, near Golden Square, and the field itself was for practical purposes bounded by Great Marlborough Street, Dean Street, Brewer Street and King Street. In this small area there were over 500 cholera deaths in ten days. Snow called it "the most terrible outbreak of cholera which ever occurred in this kingdom". It began on the night of August 31–September 1. During the first three days the number of persons attacked who subsequently died was 56, 143 and 116 respectively. The mortality would have been very much greater had not most of the population left the area. Snow immediately suspected the water of the Broad Street pump as the cause. On the evening of September 3 he examined that water, but found so little organic impurity that he hesitated to come to a conclusion. Finding, however, that the water showed more evidence of impurity during the next two days, he obtained from the Registrar-General the names of the diseased persons, and he carried out an investigation on the source of the water consumed by each. This enquiry showed that the incidence of cholera was only among persons who drank the water from this pump. On September 7 he had an interview with the Board of Guardians of St. James's parish, and as a result of what he said the pump handle was removed on the following day. The incidence of new cases ceased almost at once. Snow gives an excellent spot map—possibly the first use of a map for this purpose—showing the distribution of cases (fig 1).

There were several features of the outbreak which Snow used in an admirable manner to support his thesis. A workhouse in the area was surrounded by houses in which cholera deaths had occurred, yet there were only five cholera deaths among the 535 inmates: the Broad Street pump was not used as a water supply. A brewery in Broad Street which employed over seventy men had no definite cholera cases: there was no evidence of the men having drunk the water from the suspected pump. A very interesting case was that of a lady who had not been in the Broad Street neighbourhood for months. She preferred the Broad Street pump water, and a cart took a large bottle of it daily to her in her West End residence. She drank the water on Thursday, August 31, was seized with cholera on the Friday and died on the Saturday. A niece who was visiting her also drank the water, was attacked, and died. The pump-well was later examined by an expert, but no direct connexion between sewers and well was found.

Snow then proceeds to discuss the relationship between cholera deaths in various London districts and the water supply to these districts—a practical application of his previous suggestions. In 1854 most of London south of the Thames was supplied by two water companies; the Southwark and Vauxhall Company, which drew its water from a polluted section of the river near Battersea Fields; and the Lambeth Company, which obtained its supply from much farther up the river at Thames Ditton. In a certain area of London the pipes of the two companies ran side by side, and the last house had a choice of two supplies. In 1854, Snow assisted by Dr. J. J. Whiting, visited every house in which a cholera death had occurred and ascertained the identity of the supply used. As a result of this survey Snow showed that, during a seven-week period, the incidence of cholera deaths in houses supplied by the Southwark Company was 315 per 10,000 houses; in those supplied by the Lambeth Company 37 per 10,000; and in the rest of London, 59 per 10,000. This is one of the earliest and most perfect examples of a field investigation in epidemiology. As he says it is "on the grandest scale".

Snow's work is marked by accurate observation, careful reasoning, and logical deduction. Any suggestion that his contribution to the epidemiology of cholera consisted in removing the pump handle in Broad Street is far from the mark.

Social results of the cholera.—Like the Black Death, the cholera epidemics in the nineteenth century in this country, because of the wide dispersion of the infection throughout the land, the suddenness of the outbreak, and the supposed association with housing conditions and filth, had most important social and economic consequences. It is admitted that the 1832 outbreak was the real spark which lit the tinder of the budding philanthropic movement, culminating in the social reforms and the foundation of the official public health movement, seventeen years later. As a stepping-stone to a new age, it is interesting to note that cholera played a direct part in the formation of a great insurance company. The Rev. James Gillman was the son of James Gillman, the Surgeon of Grove House, Highgate, who was the friend and host of Samuel Taylor Coleridge. In 1847 Gillman became Vicar of Holy Trinity,

Lambeth, and there he passed the period of the second cholera epidemic. It is recorded that for three weeks he never returned to his home for fear of carrying the contagion to his family, and during this time he slept on a sofa in the surgery of the parish doctor. His experiences led him to consider the possibility of providing a fund for stricken families on the principle of life insurance. Gillman worked out his scheme with Henry Harben, who was then the secretary of a small and struggling insurance company which was called the Prudential. The new scheme was based on the weekly payment of small sums from one penny upwards, and in 1850 Gillman became the Chairman of the new company. At his death in 1877 the weekly payments amounted to over two million pounds per annum [37].

To sum up, the early Victorians, already beset as they were by the problems which followed in the train of industrial expansion, were confronted during the short space of thirty-odd years with four major epidemics of a new and loathsome disease. These epidemics caused the deaths in England and Wales alone of 21,800 persons in 1832; 53,292 in 1848-49; 20,099 in 1853-54; and 14,378 in 1866. Their success went hand in hand with the foundation of English public health, and with the building up of quarantine and other measures which have kept this island almost inviolate for eighty years.

Epidemiology of Cholera. [Summary]

By Major-General Sir JOHN TAYLOR, C.I.E., D.S.O., I.M.S. (Retired)

THE main features of the prevalence of cholera are:

- (1) Its continuous existence in permanent endemic form, only in certain limited and fairly well-defined areas of India and the Far East.
- (2) Its repeated extensions in epidemic form, mainly by continuity of land-spread over artificial frontiers, in a vast and highly populated area, comprising India, China and the countries adjoining, without the establishment of true endemicity, and
- (3) Occasional extensions west of India by land and sea routes, which have been infrequent and limited in duration in recent years, recession always occurring with subsequent complete freedom from the disease.

The basic problem of cholera is that of the endemic centres in which alone infection is permanently maintained; but for their existence cholera would presumably die out completely in time. They present a unique feature, for a bacterial disease capable of wide epidemic spread, in their limited and special localization. A combination of factors must exist there that favours the persistence of infection, similar favourable conditions apparently not obtaining in any other part of the world. No full explanation of this special localization has yet been obtained although correlation with certain climatic factors has been shown.

The two major endemic centres are in Lower Bengal and in part of the Yangtze Valley. Other minor centres have been designated but their status in that respect is less well defined. A region would be considered "endemic" in which over a very prolonged period there is a continuous low level of incidence with seasonal rise to epidemic level.

When spread occurs from the endemic areas, or from places previously infected from them, cholera experience is characteristic for each area infected and varies with climatic, geographical and other conditions. Some areas are more favourable than others for the persistence of cholera infection for a considerable period, and when a cycle of infection is occurring such an area will present the same risks of dissemination of infection as the permanent endemic centres. Their significance is not, however, the same as the centres that form the permanent reservoirs of infection.

There is no evidence that recrudescence of cholera can occur in the sense that a fresh outbreak can develop after a prolonged period of freedom from human cases without a fresh introduction of infection. Extensive field investigations in India, carried out in both endemic and epidemic areas have failed to show the presence of the vibrio except in close relation to the human case of cholera; the persistence of the vibrio in the human intestine and in water has been found to be of limited duration. The general indication obtained from recent investigations is that infection is maintained by the chain of human cases, convalescents and close contacts excreting the vibrio with, in some cases, short periods of intermediacy in water.

The problem of control in Asia.—The main spread of cholera in East Asia occurs by extension of infection over artificial land frontiers of countries and provinces in continuity with the endemic centres, or areas infected by them, under conditions in which quarantine control measures cannot be applied effectively. The existence of an endemic centre is a permanent source of danger to neighbouring areas which are put at a continuous risk of an epidemic disease against which they are not in a position to take primary action. The obvious policy to adopt for the prevention of cholera is to concentrate the main measures in the centres in which infection is permanently maintained, with the object of eliminating the source. The Governments of territories in which endemic centres are situated have a responsibility in the matter towards their neighbours, and to world health in general, that should be recognized. The matter might suitably come within the purview of the World Health Organization (WHO) with a view to assistance in investigation of the conditions in some of the endemic areas and of help in co-ordination of measures, where this help may be required.

The control of spread to the West.—In successive pandemics of cholera three main lines of extension have been recognized:

- (1) From India through Afghanistan and Iran to the Caspian and Caucasus and on to Russia.
- (2) By the Persian Gulf to Iraq and on to Syria and Turkey and the Mediterranean, and
- (3) By the Red Sea route to Egypt.

Subsequent spread resulted in scattered incidence, often with considerable mortality, in many parts of Europe and infection was even carried to the American Continent on occasions.

By the first of these routes, the long land route from India, infection has not been carried to Egypt for many years. The route does not at the present time constitute a major danger, but should be watched. Iraq has been infected eight times in the present century by sea traffic from India, the last outbreak being in 1931. Active measures were required to prevent onward land spread to Syria and Turkey on those occasions. With improving communications the risk of spread in future may increase. The short sea journey from India to the Persian Gulf ports is a factor facilitating introduction of cholera to Iraq. The main safeguard will be the strict enforcement of quarantine measures in relation to the risk that exists. This line of introduction to the West is definitely important and will require to be watched carefully.

On the third route by the Red Sea the danger at one time was mainly of introduction of cholera to Egypt by the pilgrims returning from the Hedjaz by land or by a short sea voyage at times when the Pilgrimage to Mecca was infected. Successive severe epidemics were caused in Egypt in this way, the last occurring in 1902, although the Pilgrimage was also affected in 1907, 1908, 1911 and 1912. Cholera has not occurred on the Pilgrimage since 1912. This prolonged freedom from cholera is a striking example of the value of quarantine measures designed to meet special circumstances and risks, and full reliance on them has been justified. Important points in present practice are: (a) the detention of the pilgrims at the port of embarkation in India for five days before proceeding on board ship, and (b) the subsequent call at the quarantine station at Kameran on entering the Red Sea and before proceeding to Jeddah for final disembarkation.

The risks that may exist of importation of cholera to Egypt by the direct sea route from India or the Far East may be considered in relation both to the actual cholera case and to the individual, either a convalescent or a contact, who may continue to excrete the vibrio in his stools. On the latter point the question of the cholera carrier arises.

It is not of course possible to assert dogmatically that occasional cases of prolonged excretion do not occur but there is no evidence that individuals have been responsible for the production of successive groups of cholera cases for long periods after their first infection. In this respect the chronic carrier state has not been shown to exist in cholera in the way it does in typhoid. The epidemiological characteristics of cholera would be widely different from those that have been observed if the chronic carrier acted as a definite agent in transmission. From a fresh study of the period of excretion of the vibrio by cholera convalescents and contacts which was undertaken in India in 1939 it would appear to be five days in the majority of cases, but the vibrios may still be present up to two weeks, or slightly longer. These observations may be employed in assessing the risks of carriage of infection in the course of the long sea route from India to Suez, the duration of which is over seven days.

A person incubating cholera at the time of embarkation in India would develop cholera on board ship before reaching Suez, the incubation period being taken as up to five days. Dr. Morgan and Dr. Balfour Kirk have obtained for me information of such occurrences in the course of voyages from India, Saigon and Abadan and vessels have arrived at Suez with cases on board necessitating quarantine action. Provided the occurrence is recognized or suspected the appropriate quarantine procedure should provide adequate protection against the introduction of infection. In the case of convalescents and contacts who may excrete the vibrio in their stools, the period of major risk due to persistence of infection acquired before embarkation will be passed before completing the voyage to Suez. The maintenance of infection on board ship by the occurrence of a mild case or two, not diagnosed or suspected, is a possibility to be kept in mind; infection might be introduced in this way. The protection against this will be the effective action of the quarantine staff in the detection of any suspicious occurrences.

A new risk of the spread of cholera has been introduced by modern developments in air travel, but it will usually be easy to trace the movements of passengers and any possible contacts with cholera. The time factor in regard to infectivity that I have mentioned in relation to sea travel will also apply in the case of air travel. The main risk would be the development of a clinical attack of cholera by a passenger after departure from the airport, in an area where conditions are favourable for the establishment of infection and subsequent spread. It is unlikely that a very recent convalescent would be permitted to travel but a positive contact might arrive by plane in an infective condition.

So far we have no definite information on how infection was introduced to Egypt at a time when the disease had not been reported as occurring in any other country west of India. Air or sea carriage from the East must be presumed.

Anti-cholera inoculation may usefully be employed in quarantine practice, with adequate certification of performance. Statistical evidence of its value has been somewhat limited up to now, but a report has just been published in India on the results of a statistical examination of its prophylactic value, based on very large figures. The report has not yet been received

in this country but it is understood that definite evidence of a considerable degree of protection is presented. The possession of an inoculation certificate does of course ensure complete freedom from risk.

Bacteriological and Immunological Aspects of Cholera.

[Summary]

By P. BRUCE WHITE, B.Sc., F.R.S.

IN the nineteen-thirties an international reinvestigation of *Vibrio cholerae*, its serology and relation to cholera, was undertaken, which culminated in the extensive field trials and investigations which Sir John Taylor organized in India.

At this time two items of information were waiting general application to laboratory practice. On the one hand, first Balteanu, then Shousha, Abdoosh and Gohar in succession had successfully applied to the vibrio the receptor analysis methods of Weil and Felix and on the other Kabeshima and a series of later Japanese observers had pointed out that the classic vibrio occurred in the closely related but serologically different forms which they termed the Original, Intermediate, and Variant types.

As participants in the International Investigation of 1934-35 Dr. A. D. Gardner and I confirmed in detail the findings of all these workers on an extended series of vibrio strains of varied provenance, added certain novelties of our own and were able to present the whole in one picture and to offer some suggestions as to the best methods of utilizing the newer knowledge in practice.

The essential points established were the relative specificity of the O agglutination reaction and the existence of Inaba and Ogawa subtypes of cholera and El Tor vibrios. The reason for many past discrepancies in the identification of cultures was that those who had read their agglutination tests early had recorded the specific reactions of the O antigen; those who had read them late registered the wide range of H non-specificity.

Gardner with his Indian colleague, Venkatraman, armed with the new knowledge, began what Greig had formerly attempted, a serological classification of the vibrio world. They succeeded in classifying the majority of the available vibrio strains from cholera patients, healthy subjects and water sources into six O agglutination groups of which *V. cholerae* and *V. El Tor* with their subtypes formed Group I.

At a meeting arranged by the Ministry of Health at which Sir John Taylor was present Dr. Gardner and I took occasion to urge that a pure O anti-cholera serum, or preferably the separate O antisera of the Inaba and Ogawa types, formed the proper reagent or reagents for the recognition of *V. cholerae*. The result was that at Sir John's request I undertook to prepare, not pure O antisera, but pure O antigens, which might be supplied to India and all others interested for the local preparation of valid diagnostic antisera. Dr. Gardner undertook to check the properties of my vaccines—which we rather flamboyantly called "standard O antigens"—to issue them as required from the Standards Laboratory, Oxford, and to collect and analyse any reports that might come in. From that time the O-Inaba and O-Ogawa antigens have been dispensed as requested from the original bulk preparations amounting in each case to about an ounce of dried, alcohol-extracted, steam-treated, ether-washed powder of which the bulk still remains in hand.

It is sufficient to say that, whatever other problems remained unsolved, the extensive trials which Sir John Taylor organized in India completely vindicated the hope that the sera raised against these and like antigens would give to the search for *V. cholerae* a precision hitherto lacking. The results have been set out in detail in the *Indian Journal of Medical Research*, 35, 3, July 1947.

At their first differentiation there was some suspicion that the Original or Inaba type of *V. cholerae* might be the organism of epidemic cholera, the Variant or Ogawa type that associated with the sporadic case. This was not supported by later Japanese observations; nevertheless there clung the suggestion that the Ogawa type might be a *mitis* form responsible for outbreaks of relatively mild disease. There does not seem to be any evidence either from the Japanese or later Indian investigations that this is really the case. The doctrine grew up that the type concerned in any epidemic was fixed though there might be mixed epidemics due to collateral spread of more than one type of the vibrio. For instance in the great Shanghai epidemic of 1932, 12 of 15 strains isolated in the early phase and 48 of 53 strains isolated in the later phase were of the Hikojima or middle type, the remainder being Ogawa. It was argued that the epidemic had kept its balance and Kuroya and Ono wrote of the "inalterable character of the serological types of vibrios". In India, where Sir John arranged for the distribution of type monospecific antisera, it seemed that the Inaba

and Ogawa types each had their more or less distinct zones of influence though each made occasional epidemic incursions into the territory of the other; in some outbreaks the singleness of the epidemic type seemed absolute, in others a few cases due to the sister type were encountered; some outbreaks were frankly mixed.

In his first description of the Original and Variant subtypes Kabeshima had stated that they were transmutable and he gave an instance in which the Variant type had yielded the Original type during transfer in media containing its homologous antiserum. Later workers, probably believing that in 1917 Kabeshima could not possibly have known enough about vibrio serology to understand his observations, have brushed this statement aside and have assumed the distinctness and fixity of the subtypes. I myself made several attempts to check his view without success, obtaining only, from the type cultures exposed to their antisera, the salt-agglutinable "rough" variants in which the O specificity of the organism is lost. But during a recent visit to India, Dr. D. L. Shrivastava, Biochemist to the I.R.F.A. Cholera Inquiry, and I applied to the type strains, not their full sera, but their monospecific antisera from which the common antibody had been removed, so focusing the serous influence on the type-specific antigen. Without difficulty we converted every one of 13 Ogawa type cholera and El Tor vibrios to the Inaba persuasion; and though we were unable so to alter Inaba type strains to the Ogawa type we found it possible to induce 4 of 8 strains of the Intermediate type, stemming from an outbreak in Calcutta, to make this change. Quite clearly the types are not separate species or subspecies but phases of a single species—something like the specific and non-specific phases of the Salmonella. Incidentally the instance is interesting from the point of view of basic serology in that, while such changes and the modifying influence of serum are well known in the case of the presumably protein flagella antigens, this would seem to be the first in which they have been observed to affect the polysaccharide-lipoid O complex.

I rather suspected that when platings from cholera cases were carefully examined we should find that in quite a number more than one type would be found as a result of spontaneous variation during pathogenicity. In the careful examination of about 100 cases of the spring epidemic at Calcutta, shared equally between the Ogawa and Inaba types we were, however, unable to discover a single instance of "mixed" infection. What bearing the now known transmutability of the types has on the importance to be attached to their differentiation in the field and what bearing it has on the proper composition of cholera vaccine it is difficult to say.

To pass on: following up Gardner and Venkatraman's classification by O groups and Heiberg's classification based on fermentation and non-fermentation of mannose, arabinose, and saccharose, and once more applying the cholera red and V.-P. tests of the old masters, Sir John Taylor and his co-workers were able:

(a) To show that a vibrio which ferments mannose and saccharose but not arabinose and is at the same time cholera red positive and V.-P. negative and non-hæmolytic is in all probability a true cholera vibrio of O group 1.

(b) To classify 311 of 558 vibrio strains inagglutinable with O group 1 serum and drawn from cholera cases, healthy people and water sources into 33 O groups, so making it possible to argue the role of these in the causation of cholera by consideration of the origins of their several component strains. The conclusion reached by Sir John Taylor in assessing the collected results of this and other series of examinations was that, with one possible exception, no case for the cholerigenic activity of any of these could be made out.

In comment on this conclusion, to which I cannot but in general concur, it must be admitted that in India many experienced cholera workers are by no means so convinced, and for one reason or another cling to the view that vibrios other than *V. cholerae* may from time to time contribute to cholera.

Dr. Melville Mackenzie described the measures taken to deal with the Egyptian outbreak on the international level. The Interim Commission of the World Health Organization offered help to the Egyptian Government and on their request undertook to purchase cholera vaccine for them. This method of purchase had been satisfactory but in the absence of any standards the Egyptian authorities had been asked to test the antigenic efficacy of the vaccines received. The Commission's Expert Committee on Quarantine held an emergency meeting at which the Egyptian Under-Secretary of State for Quarantine gave an account of the epidemic. The Committee were impressed by the extent and thoroughness of the steps taken by the Egyptian authorities. It appeared that some countries had imposed restrictions on travellers from Egypt which greatly exceeded the provisions of the International Sanitary Code. These measures were inspired by fears which largely arose from insufficient knowledge of the true epidemic situation; in order to allay them infected countries should provide prompt information to the WHO for transmission to national

health authorities. The Committee gave advice on precautions against the spread of cholera in aircraft by infected water, passengers or flies.

In England and Wales all M.O.s.H. were informed of the occurrence of the outbreak and of its course. Advice was given about dealing with ships and aircraft arriving from an infected port. Travellers arriving by air were not kept under surveillance until the occurrence of suspected cases in Italy and Australia when it was applied to those who had, in the five days before arrival, slept one or more nights in Egypt. Cholera inoculation prior to arrival was not insisted upon. Other countries had done so and in some countries inoculated persons had been exempted from surveillance but this seemed to place excessive confidence in the protective value of the vaccine. The Ministry of Transport had warned ships calling at Egyptian ports that as far as possible they should not allow those on board to land or take on water, fresh fruit or vegetables. The import of baled cotton, sacked rice, rags and dates had not been prohibited.

Arrangements had been made for Sir John Taylor and Mr. Bruce White to visit Egypt on behalf of the Ministry of Health and the Medical Research Council in order to study the results of the use of sulpha drugs and the value of DDT spraying and to carry out researches on the cholera vibrio. There was need for scientific investigation of the length of the cholera vibrio's viability (1) on flies particularly when carried by aircraft, (2) in sewage both crude and during treatment, and (3) on fresh fruit and other commodities. The Expert Committee on Quarantine was interested in these questions and in the standardization of cholera vaccine and the Commission had been offered some 6,000,000 French francs by the Office International d'Hygiène Publique for epidemiological research with cholera as a first objective. Medical supplies to the value of £5,000 were being flown to Egypt within the next few days.

Sir Leonard Rogers showed maps illustrating the spread of cholera epidemics from India to Europe during the nineteenth century. With regard to the present outlook the speaker said that cholera incidence might be expected to decline in Egypt during the latter part of November and to die down in December and January, but there was a serious danger of its breaking out again in that country in 1948 in the spring or early summer with rising temperature and absolute humidity, but the geographical conditions were favourable to its control by modern methods and to the prevention of its spread over South Europe such as occurred in 1883-84. There was, he thought, grave danger of the present epidemic in the troubled and chaotic conditions of the Punjab being carried by the invading North-West Frontier tribes to Afghanistan, and recurring there in the spring of 1948 with spread by the usual overland route to Southern Russia, whose very lengthy land frontier would be most difficult to protect against invasion by the disease in spite of medical advances in Soviet Russia. Overcrowding in Russian towns would be favourable to the spread of cholera if it gained a firm foothold in that vast country. That line of spread might prove to be more dangerous than from Egypt, but it was to be hoped that modern medical science would prove equal to the occasion.

Lieut.-General Sir Bennett Hance observed that in checking the epidemic in Egypt the principles of attack were the same as those holding in India—namely attention to environmental hygiene and inoculation.

In rural India at any rate attention to environmental hygiene could be summed up in the disinfection of water supplies since, outside large towns or organized cholera camps, nothing like efficient conservancy or protection of food supplies was possible. Where piped water supplies or wells existed disinfection by chlorination was comparatively simple, but where, as in parts of India, the water supply was the village "tank" or, as in Egypt, a sweet water canal, such measures became difficult or impossible. It followed, therefore, that all the more reliance would have to be placed upon inoculation, and it was satisfactory to know that, at last, a controlled and statistically authoritative evaluation of the efficacy of inoculation was available (*see Ind. J. med. Res.*, 35, 3, July 1947, by R. Adisesan, C. G. Pandit and K. V. Venkatraman). This would appear to establish the efficacy of the measure upon which doubts had been thrown by the various authorities. Such experience as the speaker had had in handling outbreaks of cholera had certainly tended to confirm the efficacy of the measure and, in consequence, he personally had never doubted it; but the confirmatory evidence of the survey referred to was most satisfactory. A combination of environmental hygiene and inoculation had removed most of the dangers of the great Pilgrimages in India and, in areas where the water supply was "tanks", the speaker personally knew of only one method of holding the spread of cholera and that was "at the point of the needle".

[November 28, 1947]

DISCUSSION ON THE PLACE OF CHILD GUIDANCE IN THE NEW HEALTH SERVICE

Dr. Ian Skottowe, (Royal Bucks Hospital): *A case for integration.*—The Child Guidance Movement has been active, in organized form, in this country continuously since 1929. It has come to embrace practically the whole of the psychiatry of childhood, except gross mental deficiency. When the movement began, enthusiasm for dynamic psychopathology was keen and widespread, and this approach was blended with an attack upon social and educational factors in the psychiatric disorders of childhood. In this way the traditional team of psychiatrist, psychiatric social worker and educational psychologist came into being, and there was a tendency for child guidance to become highly specialized and somewhat isolated, not only from general medicine, but also from general psychiatry.

In the intervening years knowledge has been gained and viewpoints have broadened so that those who deal with the psychiatric disorders of children must take into account a wider range of specialties than is implied by dynamic psychopathology alone. The relevance of organic neurology, special disabilities affecting the speech function, metabolic disorders, endocrine dyscrasias and nutritional problems is important. More recently, electroencephalography, audiometry and the assessment of motor skills have received close attention.

On these grounds, there is a strong argument in favour of integrating child guidance with the New Health Service, and offering it as a customer service to education authorities, since the latter, although they have an indispensable contribution to make, could not, within the school medical services, provide all the facilities that the maladjusted child may need, without excessive duplication. Other advantages of this integration are that it diminishes the chance of unfortunate results arising from too early and too excessive specialism within a specialty; it brings the family doctor right into the picture, for it is often he who is first consulted by the parents; and it provides facilities for psychiatric interviews with the parents themselves—often an important part of the treatment of the child.

Clinical features.—A survey was made of a random sample of 100 consecutive patients up to 16 years of age, seen at the Psychiatric Department of the Royal Buckinghamshire Hospital, Aylesbury. Patients were drawn mainly from the static population of the district, evenly divided between rural and urban elements. 64 of the children were referred by their family doctors; 17 by other hospital departments (i.e. the presenting picture was that of an illness other than a psychiatric one); 31 of the children were between 14 and 16 years of age. The clinical forms of illness or maladjustment included: anxiety states, 24; behaviour problems and habit disorders, 40 (8 enuretics); special disabilities, 17; mental defect, 14, + 4 others of subnormal intelligence (10 of these were first diagnosed in the 14 to 16 age-group); depressive syndromes, 4; toxic-exhaustive states, 3; schizophrenia, 3. 33 of the patients had somatic disorders, with varying degrees of relevance to the psychiatric syndrome, which needed the attention of specialists in other branches of medicine; and a further 9 had symptoms requiring somatic investigation. 90 of the patients were treated as out-patients; 10 needed residential treatment (3 mental hospital, 2 general hospital, 5 in a hostel, or residential special school); 19 of them needed the services of an educational psychologist, and 18 needed social service in its therapeutic, as contrasted with its investigational, aspects. It is suggested that the features of this clinical material clearly warrant general hospital facilities being available for maladjusted children.

Practical proposals.—The Joint Memorandum of the Royal College of Physicians, the British Medical Association and the Royal Medico-Psychological Association (1945), and Blacker's Survey (1946) suggest that the unified form of child guidance clinic of the past education respectively, but sharing at the clinical level a common technical staff. There would be a child guidance centre, managed by the education authority, where an educational psychologist would do the preliminary grading of children's aptitudes and abilities. Any child who presented active symptoms, or who was clearly maladjusted, would be referred to the school medical officer, and through him a psychiatrist would be available as a consultant at the centre. Should it be thought that the child could more suitably be treated at the psychiatric department of a general or special hospital, he could then, on the psychiatrist's advice, be referred there. This branch of the psychiatric department of the general hospital would be known as the child psychiatric clinic and, ordinarily, it would be the same psychiatrists who would attend at both places—the centre and the clinic. Should it happen that a child was referred in the first instance to the clinic, before his difficulties had been spotted at the centre, and should the psychiatrist at the clinic consider that educational factors were important in treatment—for instance, the services of an educational psychologist, or administrative problems, such as change of school—he should then approach the education authorities through the school medical officer. Thus there would be two-way collaboration, which would preserve continuity of treatment for the child throughout. A psychiatric social worker should be attached to the clinic rather than to the centre.

It has been said that these proposals involve dual administration, but this is not in fact so. Dual administration would mean having two people in charge of one organization. What is proposed here is that each should be in charge of his own, and that there should be easy inter-availability at the school level, the school medical officer being the administrative go-between.

Above all, the management of the child who needs psychiatric attention should be effected under the guidance of a suitable psychiatrist from the start, through whatever channel help may be sought; so long as this aim is realized, it matters little who is in administrative charge of the centres or clinics in which the psychiatrist works. It should be no more difficult for a doctor from the health services to act as a consultant to the child guidance centre, without being in charge of it, than it would be for him to be a consultant to an old men's home, an insurance company or one of the fighting services, nor should there be any difficulty about a psychologist from the education authority being available to a health organization, if he or she has a part to play in the treatment of a patient.

BLACKER, C. P. (1946) *Neurosis and the Mental Health Services*. London.

Dr. A. A. E. Newth (Nottingham Education Committee): Child guidance has two main objects—the diagnosis and treatment of maladjustments in children, and prevention and treatment through parents, teachers and others who have the care of children.

The majority of maladjusted children are basically normal. Psychosis is rare in children. The potentially psychotic child may be maladjusted, but the vast majority of maladjusted children are not at all psychotic nor are they ever in any danger of becoming psychotic.

The approach should therefore be not from the adult suffering from the severer forms of psychosis towards the child who is seriously disturbed, but from the normal child towards the one who has become less well balanced.

The medico-psychological or even purely medical aspects of many of the cases cannot be ignored and accurate medical diagnosis is essential. In treatment, also, the deep psychotherapeutic practices sometimes involved are dangerous without the supervision of a medical psychiatrist.

Some of the plans suggested during the last few years involved the taking over of the whole work by a mental health service catering for persons of all ages and of all grades of mental efficiency and deficiency and of all kinds of mental disturbance from the milder forms of maladjustment in children to the grossest forms of incurable psychosis and dementia in adults.

Is such planning really sound? Is the physician preoccupied with the more dramatic forms of mental disturbance and disease in adults as seen in mental hospitals likely to be sympathetic with the almost normal misbehaviour and psychological mishaps and educational misfits of children? Will not parents, teachers and doctors be reluctant to refer cases to a clinic which they suspect is even remotely connected with mental deficiency or insanity?

Dr. Blacker has clearly shown that the adult mental health service is unable to cope with the large amount of neurosis that exists to-day. It seems scarcely logical to overburden it still further with maladjusted children.

It has been suggested as a corollary that there should be child guidance clinics within the educational system run by educational psychologists who are to be entrusted with the diagnosis and treatment of those children not showing *prima facie* signs of mental instability. Such a policy is open to the strongest criticism as it places on lay psychologists a responsibility with which they should not be burdened however capable they may be.

Many education authorities like my own have established child guidance centres under the supervision of the school medical officer with a team comprising the educational psychologist, the psychiatric social worker and the child psychiatrist, under the technical supervision of the last-named, with lay psychotherapists, educational therapists and speech therapists, in a clinic separate from, but close to, the main school health clinic. The educational psychologists spend a great proportion of their time in the schools in contact with the teachers dealing with other educational problems. Thus the closest liaison is maintained with both the medical and educational aspects of the work.

The educationally subnormal child for the special school and the ineducable mentally defective are kept out of the scheme, and the occasional psychotic is referred to the mental hospital physician.

If, as is not infrequently the case, the seriously neurotic or even perhaps psychotic parent needs treatment she is referred to the mental hospital physician, although help can be given to the worried parent in the clinic by the psychiatric social worker.

Hostels are available for those children who cannot be suitably treated at home; a lien on several hostels is invaluable so that there may be a choice for varying types of cases.

For the child who is ailing physically, the whole gamut of the school health service is available including residential special schools where prolonged physical treatment can be given.

In my area a large proportion of the cases are referred by the teachers who are the first to observe unusual symptoms in school or to receive complaints from parents of difficulties in the home. In other types of clinics there would be a tendency for cases to be referred by doctors outside the school health service only when the condition had become well established.

The large children's or specialized hospitals are called upon for accurate neurological or other examinations or in-patient observation that prove to be occasionally necessary.

As for the much-needed staffs, the training of these is supplied by the teaching child guidance clinics of London and elsewhere.

It is to be hoped that the family doctor will himself be willing in the future to play a greater part in the prevention of maladjustments in the family and their treatment in the early stages.

The aims of the Education Act are to provide a complete service for children at "all ages, abilities and aptitudes", and child guidance is an essential part of such a Child Health Service, foreshadowed by Sir Wilson Jameson to be a part of the National Health Service.

Dr. E. M. Creak: Blacker, in his book, "Neurosis and the Mental Health Services", outlining his conception of plans to deal with children's problems, discusses the provision of educational clinics to deal with the simple problems shown mainly in relation to school, and child psychiatric clinics attached to a hospital and under the control of the Health authority.

While this implies that educational problems may be simpler to deal with than others, such is not necessarily the case, and it is impossible to judge accurately the "difficulty" of a child's problem, either on the basis of the manifest severity of symptoms, or by observing their precise nature. Since prediction is so uncertain, it seems important that every child guidance clinic should have an experienced psychiatrist available. The separation of problems into "educational" and "psychiatric" is unsound, and the team of psychiatrist, psychologist and social worker seems likely still to give the best approach for the initial survey. It would, however, be undesirable that the new National Health Service should attempt to cover the whole field of child psychiatry with a uniform type of clinic.

Among others the pædiatric hospital will get its full share of psychiatric work, more especially since nervousness in children is so commonly shown by a physical manifestation. The pædiatrician will tend to be consulted in the problems of infancy, such as feeding difficulties, and, even at this early stage, the mother is herself often aware that she needs psychological rather than physical help in establishing normal habits, and a secure adjustment during early childhood.

It is to the pædiatric hospital again, rather than to the psychiatric, that the more severe disorders of early childhood present themselves. Such children often give a history of

Practical proposals.—The Joint Memorandum of the Royal College of Physicians, the British Medical Association and the Royal Medico-Psychological Association (1945), and Blacker's Survey (1946) suggest that the unified form of child guidance clinic of the past should give place to two organizations, each administered by its own authority, health and education respectively, but sharing at the clinical level a common technical staff. There would be a child guidance centre, managed by the education authority, where an educational psychologist would do the preliminary grading of children's aptitudes and abilities. Any child who presented active symptoms, or who was clearly maladjusted, would be referred to the school medical officer, and through him a psychiatrist would be available as a consultant at the centre. Will not parents, teachers and doctors be reluctant to refer cases to a clinic which they suspect is even remotely connected with mental deficiency or insanity?

of social and vital statistical data for Willesden with those of London as a whole show that this borough can be regarded as typifying the metropolitan population.

When the dates of death and the homes of the fatal cases were examined, it was found that they were not randomly distributed in time or place. They tended to be aggregated in both ways: about one-quarter of the deaths happened in 17 of the whole 468 weeks reviewed, and they occurred with unexpected frequency in near-by houses or in short streets. From both standpoints there was evidence of epidemic association, and it seems reasonable to believe that some local common factor, of which the most likely is some specific infective agent, is responsible for the frequent occurrence of such individually small, but numerous, focal outbreaks as those recorded in Willesden.

Assuming that an important fraction of the deaths from infantile enteritis have an infectious aetiology, I shall now review briefly the relative importance of the three forms—neonatal diarrhoea, parenteral infections and infectious enteritis—in London in recent years.

The form known as "neonatal diarrhoea" was first recognized by Frant in New York in 1937, and since then numerous institutional outbreaks have been recorded. In New York, Frant found that while the mortality of infants under 1 year from enteritis had been falling steadily, that of infants under 1 month had been rising. In London, the same reciprocal trends are now becoming apparent. In the decade 1930–39, about one in twenty of the deaths of infants under 1 year took place in the first four weeks of life. In 1940, it rose to one in six and has since remained high. The change in proportion can only be partly accounted for by the fall in enteritis mortality between the ages of 4 weeks and 1 year. It has also been brought about by a rise in mortality of infants under four weeks—which is now substantially higher than before the war—a possible result of the increase in institutional midwifery in recent years. It thus seems likely that the importance of neonatal diarrhoea is increasing both absolutely and relatively, but it has had little effect yet on the domiciliary enteritis of a suburban area.

The parenteral lesions that have been most often incriminated as possible antecedents of enteritis have been in the upper respiratory tract and its associated sinuses. In Smellie's series, one-quarter had otitis media or mastoiditis and one-seventh bronchitis or pneumonia, at the time of admission to hospital. In Campbell and Cunningham's series, the incidence of tonsillitis, laryngitis, bronchitis and pneumonia was much the same, but otitis media was much less common. There is thus ample evidence for the frequent association of such parenteral infections with enteritis—the question is: Which condition is to be regarded as primary?

A further reason for interest in the possible connexion between parenteral infections and enteritis is the rise in enteritis mortality in the first quarter of the year in London in recent years. Twenty-five years ago the mortality for the quarter January to March—the season of maximal respiratory infections—was 1·7 per 1,000 births. Just before the war, it had risen to 3·6 per 1,000—more than twice its former figure. Yet in spite of this rise there seem to be several reasons for doubting whether these parenteral lesions take a very important place in the aetiology of enteritis. Campbell and Cunningham examined their patients on admission and at intervals subsequently for evidence of parenteral infection. Amongst nearly 300 dehydrated infants, only about one-quarter had such infections at their first examination, but nearly the same fraction developed otitis media or bronchopneumonia after the symptoms of enteritis had become well established. Wishart and Smellie also have drawn attention to the frequency with which infants suffering from enteritis develop otitis media while under care in hospital. Such observations lessen the force of the evidence—much of it derived from post-mortem room studies—upon which the idea of parenteral enteritis was originally based.

In the records for infantile enteritis in Willesden, supplementary information upon concurrent pathological conditions was frequently available. Of the 285 deaths from enteritis, only 43 had records of accompanying infections of their respiratory tracts, and these cases were distributed almost uniformly in all the quarters of the year.

Lastly, when the Registrar-General's data for the decade 1929–38 are examined, there is no tendency for the mortality from infantile enteritis in London to be unduly raised in the years of raised mortality from bronchopneumonia, measles or pertussis. Secondary enteritis is a not uncommon complication of measles, so that in measles years a small, but probably very small, fraction of the deaths recorded as due to enteritis should probably have been more correctly ascribed to measles.

Smellie's "Infectious Enteritis"—the unknown enteral infection without demonstrable pathogenic organisms—is the third of the major forms. Hitherto much of the emphasis upon the infectious nature of enteritis has come from clinical experience in institutions for the care of young children. Such outbreaks, often caused by members of the dysentery group of bacteria, have provided a large proportion of all nosocomial diseases. Valuable though these institutional studies are, they must be carefully distinguished from our present

normal development for the first year or more. Soon however an apparent regression, which is often more a failure to progress, sets in. By the time they reach school age they have usually become unable to take part in normal education. They therefore do not find their way to educational clinics, where the psychotic picture would be distinguished from mental defect, but often go into institutions for mental defect because of their complete inability to adapt socially. The help given by expert psychological testing may be required at the pre-school age to differentiate these from each other, and again from children who are neither ill, nor retarded, but who appear so through sense deprivation, particularly deafness, occurring at an early age.

The general field of psychosomatic medicine increases its range, and nowhere is this more true than in pædiatrics, where asthma, cyclical vomiting, enuresis and other habit disorders abound. Nor can the psychological aspect of chronic physical illness be lightly dismissed. It has been observed by Bowlby and others (Bowlby, J., *Int. J. Psychoan.*, 25, Pts. 1 to 4, 1944) that prolonged hospitalization at an early age is very prone to produce severe affective disorders in later age, in some cases predisposing to a schizoid withdrawal, in others frankly delinquent, anti-social conduct. Nevertheless, recurrences of a physical illness may often be precipitated by the maladjustment resulting from long periods away from normal surroundings of family and school. Here, the value of a psychiatric investigation will be in the direction of avoiding or anticipating breakdown in two directions.

First, during the child's stay in hospital, much can be done to minimize those factors tending to produce either a withdrawal into fantasy life or an unnatural dependence on the protective aspect of hospital care. Secondly, the extremes of fear and rage, love and hate, can be both understood and avoided by personnel trained in a real knowledge of normal developments in the young child.

Such understanding should form part of the training of every pædiatrician, and of nurses having the care of sick children. Not only must they be aware of the normal capacities appropriate to different ages, but they must acquire an understanding of the dynamic factors which are present in the common disorders, and in deviations from the normal.

It is difficult to see how this can be done unless a department of child psychiatry exists as a normal working department of the children's hospital. There the psychological angle of an apparently wholly medical problem can be seen, studied, and treated. Both diagnosis and therapy must be available in order that ordinary mechanisms of psychological disorder may be understood.

[January 23, 1948]

DISCUSSION: THE ÆTIOLOGY OF INFANTILE ENTERITIS

Professor G. Payling Wright (Department of Pathology, Guy's Hospital): Until some years after the 1914-18 war, infantile enteritis mortality was dominated by epidemics of summer diarrhoea which reached their peaks in the late summer. These seasonal epidemics have not taken place in London for twenty years, and have almost disappeared also from other large English cities. Although this formerly preponderating component of infantile enteritis is no longer recognizable in the Returns of Infectious Diseases there still remain many deaths in this category of the Registrar-General's Reports. In the County of London, between 1934 and 1938, they averaged more than 700 annually, and even in the war years, when births in London were much reduced, they remained between 300 and 400 yearly.

There is general agreement that epidemiologists use the term "infantile enteritis" to cover several diseases of different ætiology. In some cases the enteritis seems to be primary, in others it is secondary to disease processes elsewhere in the body. In some infants it seems to arise from dietetic causes, in others an infective agent, such as a dysentery bacillus, provokes its onset. Smellie, in his study of enteritis in Birmingham, classified his cases into four categories: "Infective", "Infectious", "Parenteral" and "Dietetic"; with the addition of "Neonatal Diarrhoea", his scheme will be followed here.

My contribution to this discussion on ætiology will be to try to derive some estimate of the relative frequency of deaths from neonatal, infectious and parenteral causes, as they are happening in London at the present time. Much of the material needed for this analysis was obtained through the kindness of Dr. G. F. Buchan, the Medical Officer of Health for Willesden. The data consisted of the borough records of the deaths of infants under 2 years which were registered as "Gastro-enteritis", "Diarrhoea and Vomiting", &c., all diagnoses ultimately included by the Registrar-General under "Diarrhoea and Enteritis". Comparisons

prevalent in the locality at the time. Such a conception of the ætiology of enteritis thus involves the conjunction of several contingencies: first, contact with a potentially pathogenic strain; secondly, the absence of any specific congenital immunity against that strain; and thirdly, the loss of aciduric flora that follows the cessation of breast feeding. This seems to accord better with our knowledge of enteritis than the conception of a single bacterial malefactor that is capable of causing enteritis in all infants infected, which has tended to dominate bacteriological investigations upon infantile enteritis in the past.

In conclusion, for the purpose of focusing discussion, I shall summarize very briefly these views on the relative importance of these various forms of infantile enteritis in London. It seems to me that, in spite of the rise in the incidence of deaths from this condition in the late winter months, there is little evidence that parenteral infections play any important part in their ætiology. On the other hand, there seems to be evidence that the neonatal form of enteritis is rising and, with the increasing use of maternity hospitals, this rise is likely to continue. But the main component of infantile enteritis in urban communities seems to be Smellie's "Infectious" form. In the past, the infective agents were spread by two main vectors—flies and man—the one seasonal and the other perennial. The former has largely disappeared, and with it has gone the devastating outbreaks during hot summers. The latter continues and maintains the endemicity of mildly pathogenic organisms that are capable of causing enteritis in susceptible infants.

Dr. S. Sevtitt reviewed the various theories of causation of diarrhœa and enteritis, classifying them as follows, viz.:

(1) The disease is secondary to parenteral infection, particularly latent mastoiditis; (2) it is a primary bacterial infection of the bowel; (3) it is a virus infection, (a) a primary viral enteritis, or (b) a generalized virus disease with secondary gastro-enteritis, and he advanced a fourth theory that it is due to nutritional deficiency combined with infection of the gastro-intestinal tract.

In summarizing the relationship between gastro-enteritis and mastoiditis he quoted the recent findings of Stewart Smith of Manchester, who found pus in one or both antra in 50% of all autopsies on infants, and who showed that it was commonly present in children dying of pneumonia or marasmus as well as in those dying of enteritis. He suggested that this form of mastoiditis is a non-specific phenomenon akin to hypostatic pneumonia and, like the latter, may be a terminal condition.

In surveying results of the bacteriological findings from the fæces he noted that no specific organism had been isolated which could be accepted as the specific cause of the disease such as *B. typhosum* is in typhoid fever. Investigations had incriminated a long list of organisms, usually non-lactose fermenting Gram-negative bacilli such as *B. proteus*, Morgan's No. 1 bacillus, paracolon bacilli, sometimes dysentery bacilli, &c. He presented a selection of bacteriological findings from various investigators in different parts of the world during the last forty years. These included the findings of *B. proteus* in 93% of cases by Metchnikoff in Paris in 1914, the isolation of dysentery bacilli in 75% of cases by Biocca and Cammerella in Italy in 1939, the isolation of *B. morgani* by Morgan and Ledingham in London in 1904, the 50% frequency of paracolon bacilli reported in 1929 by Fothergill in the U.S.A., also found by Morgan and Ledingham. He outlined the results of his own work in Dublin which included a 50% incidence of *B. proteus*, 4% dysentery bacilli, 6.5% *B. morgani* and 30% to 40% of paracolon bacilli. He found that the majority of the latter organisms could be classified serologically, that four main antigens existed and that these paracolon bacilli usually contained common agglutinins with many dysentery bacilli. Correlation of bacteriological findings with the clinical course of the disease in Dublin showed that the isolation of *B. proteus* was statistically related to the severity and fatality of the disease process.

Even the bacteriological findings in the same city at different times varied. He compared the findings of Tenbruk and Norbury in 1915 with those of Fothergill in 1929, both series at Boston—the former finding 54% of dysentery organisms, the latter 5% of these organisms but in addition paracolon bacilli in 44% of cases. Similar variable results at different times

problem—that of trying to make some estimate of the relative importance of the various forms of enteritis as they are occurring at the present time amongst infants in large urban communities. The circumstances which surround young children living a herd life in an institution are wholly different from those of the great majority of infants who live dispersed in ordinary houses and in contact with persons of all ages. The importance of infection in institutions is fully established: its importance in family life is not nearly so apparent.

The records for Willesden—a representative London suburban borough, both socially and epidemiologically—show that many of the deaths of infants from enteritis before the war were not distributed wholly randomly either in time or place, and less complete records from several other London boroughs have been found to support this conclusion. At the same time, little evidence was found in the Willesden survey of any outbreak in private houses which could properly be termed an epidemic. The outbreak which most nearly resembled one took place in the adjacent Wards 6 and 7 of the borough in the summer of 1935, when eight fatal cases occurred in a little more than three months within an area of less than a quarter of a square mile. Since the case-fatality rate for infantile enteritis about that time was of the order of 20% such a local outbreak probably led to clinical attacks in about 40 of the roughly 250 infants less than a year old who were living in the area. Although frank epidemics on their former scale no longer occur in London, and even small-sized outbreaks of the kind just mentioned are probably infrequent, there seems to be evidence in favour of the view that an infective factor is often in operation in the enteritis that is endemic in such urban communities. The instances of multiple fatal cases, such as were found in near-by houses and short roads in Willesden, as well as the raised incidence amongst twins, all acquire a certain cumulative force when taken together. It seems unlikely that so many deaths would occur in close proximity to one another unless they were connected either directly or through the intermediary of some surviving case.

Any discussion on the nature and mode of spread of an organism which might be responsible for such an infectious form of enteritis can at present be little more than speculative. The wide area of Willesden, over which more or less simultaneous fatal cases of enteritis were distributed, would suggest that any causative organism must at the same time be widely diffused, yet generally unobtrusive, in its behaviour in the general population. In comparison with what is known of the spread of nasopharyngeal bacteria in a community, little is yet known of the rapidity with which intestinal organisms, of species which are relatively harmless for adults and older children, circulate from person to person. What little evidence there is, however, seems to indicate that such exchanges are by no means infrequent. Wallick and Stuart made some observations on the persistence of particular serological strains of *B. coli* in the intestines of a subject by frequent sampling of his faecal flora. Their first identifiable strain was isolated in April, and it continued to be the predominant strain until the following September, when it was supplanted by the second. This persisted until the end of the year, when it was replaced by the third. If these observations are typical, and they are supported by other evidence of the same kind, it seems likely that the coliform flora of the human intestine undergoes frequent changes in its serological variants. It seems not improbable, therefore, that a coliform organism of a variety which is potentially pathogenic for certain infants may become disseminated freely in a restricted neighbourhood of an urban community—which shares many possible vector objects in common—without its evoking any noteworthy symptomatic reactions in the older population.

This conception of a low-grade pathogenic organism as the cause of infantile enteritis carries us back to the very carefully conducted field study of this condition that was made over thirty years ago by Peters in Mansfield. By selecting parts of the town for intensive study, he was able to obtain records over a period of about a year of the cases of diarrhoea that occurred at various ages of the population. The high rates in infancy and the more moderate rates in parents contrast with the much lower incidence in adolescents; deaths, however, were almost confined to the infants under 2 years of age. That the diarrhoeal attacks were of an infectious nature is supported by the great frequency with which multiple cases developed in the families attacked. Peters' findings are thus fully compatible with the view that strains of intestinal bacteria possessing very different pathogenic potentialities for infants and older persons are endemic in the population.

That *B. coli* itself can be highly pathogenic for newly-born infants is clearly shown by the occasional occurrence of a specific suppurative meningitis. So far as is yet known, the strain of *B. coli* which is responsible for this particular clinical manifestation is in no way distinctive, though serological studies on the lines initiated by Kaufmann in Copenhagen might lead to the identification of some particular variant of this organism analogous to that found by Pitman for *H. influenza*. Through the cessation of breast feeding and the resulting disappearance of the aciduric flora from the intestines, to which Cruickshank and others have drawn attention, the infant may become prematurely vulnerable to infection with any of the more pathogenic strains of coliform organisms that may happen to be

prevalent in the locality at the time. Such a conception of the ætiology of enteritis thus involves the conjunction of several contingencies: first, contact with a potentially pathogenic strain; secondly, the absence of any specific congenital immunity against that strain; and thirdly, the loss of aciduric flora that follows the cessation of breast feeding. This seems to accord better with our knowledge of enteritis than the conception of a single bacterial malefactor that is capable of causing enteritis in all infants infected, which has tended to dominate bacteriological investigations upon infantile enteritis in the past.

In conclusion, for the purpose of focusing discussion, I shall summarize very briefly these views on the relative importance of these various forms of infantile enteritis in London. It seems to me that, in spite of the rise in the incidence of deaths from this condition in the late winter months, there is little evidence that parenteral infections play any important part in their ætiology. On the other hand, there seems to be evidence that the neonatal form of enteritis is rising and, with the increasing use of maternity hospitals, this rise is likely to continue. But the main component of infantile enteritis in urban communities seems to be Smellie's "Infectious" form. In the past, the infective agents were spread by two main vectors—flies and man—the one seasonal and the other perennial. The former has largely disappeared, and with it has gone the devastating outbreaks during hot summers. The latter continues and maintains the endemicity of mildly pathogenic organisms that are capable of causing enteritis in susceptible infants.

Dr. S. Sevvitt reviewed the various theories of causation of diarrhœa and enteritis, classifying them as follows, viz.:

(1) The disease is secondary to parenteral infection, particularly latent mastoiditis; (2) it is a primary bacterial infection of the bowel; (3) it is a virus infection, (a) a primary viral enteritis, or (b) a generalized virus disease with secondary gastro-enteritis, and he advanced a fourth theory that it is due to nutritional deficiency combined with infection of the gastro-intestinal tract.

In summarizing the relationship between gastro-enteritis and mastoiditis he quoted the recent findings of Stewart Smith of Manchester, who found pus in one or both antra in 50% of all autopsies on infants, and who showed that it was commonly present in children dying of pneumonia or marasmus as well as in those dying of enteritis. He suggested that this form of mastoiditis is a non-specific phenomenon akin to hypostatic pneumonia and, like the latter, may be a terminal condition.

In surveying results of the bacteriological findings from the fæces he noted that no specific organism had been isolated which could be accepted as the specific cause of the disease such as *B. typhosum* in typhoid fever. Investigations had incriminated a long list of organisms, usually non-lactose fermenting Gram-negative bacilli such as *B. proteus*, Morgan's No. 1 bacillus, paracolon bacilli, sometimes dysentery bacilli, &c. He presented a selection of bacteriological findings from various investigators in different parts of the world during the last forty years. These included the findings of *B. proteus* in 93% of cases by Metchnikoff in Paris in 1914, the isolation of dysentery bacilli in 75% of cases by Biocca and Cammerella in Italy in 1939, the isolation of *B. morgani* by Morgan and Ledingham in London in 1904, the 50% frequency of paracolon bacilli reported in 1929 by Fothergill in the U.S.A., also found by Morgan and Ledingham. He outlined the results of his own work in Dublin which included a 50% incidence of *B. proteus*, 4% dysentery bacilli, 6.5% *B. morgani* and 30% to 40% of paracolon bacilli. He found that the majority of the latter organisms could be classified serologically, that four main antigens existed and that these paracolon bacilli usually contained common agglutinins with many dysentery bacilli. Correlation of bacteriological findings with the clinical course of the disease in Dublin showed that the isolation of *B. proteus* was statistically related to the severity and fatality of the disease process.

Even the bacteriological findings in the same city at different times varied. He compared the findings of Tenbruk and Norbury in 1915 with those of Fothergill in 1929, both series at Boston—the former finding 54% of dysentery organisms, the latter 5% of these organisms but in addition paracolon bacilli in 44% of cases. Similar variable results at different times

were obtained in Birmingham, Alabama, by Davison in 1919 and by Denison and De Holl in 1935. In London in 1910, O'Brien could only find *B. morganii* in 14% of cases, although Morgan and Ledingham found this organism in 50% of cases ten years previously. He argued that we are faced with the alternatives that the pathogen is a different agent from time to time and from place to place or that the disease is of uniform aetiology and is due to a primary agent or cause, the nature of which is unknown.

Dr. Sevitt next described and criticized the evidence of viral aetiology. The work of Light and Hodes in the U.S.A., who claimed to have transmitted enteritis to calves with a filtrable agent from the stools, was suspect because the agent withstood boiling. Moreover Deeney in Dublin could not get these results with similar experiments. Reimann's experiments in transmission of diarrhoea to human volunteers by the inhalation of nebulized filtrates of gargle washings and stools were criticized on his failure to isolate the subjects from the rest of the community and the prolonged incubation period of one to three weeks in half his cases. The results of Christen and Buering-Sorensen in 1946 in finding a meningo-encephalitis or aseptic meningitis in many infants at post-mortem were not accepted as proof of viral aetiology as inclusion bodies were not demonstrated. Similar changes in the brain could be of toxic or nutritional origin. The speaker added that this might still be a profitable field of investigation.

In introducing a dual concept of aetiology he advanced epidemiological, histopathological and experimental evidence. The close association of incidence and fatality of the disease with the babies of the poorer sections of the urban population, the immunity of the infants of the well-off classes, the high incidence of the disease in many good working-class suburbs (where over-crowding was *not* a factor) and the relative immunity of the breast-fed infants of even the poorer classes all suggested some underlying nutritional factor or factors. Does breast-milk contain an anti-diarrhoeal factor? The close resemblance of the liver changes in diarrhoea with those found early in the course of tropical nutritional deficiency was in support of this thesis.

Next he outlined his experimental work with young kittens. He described the reproduction of a disease in 6 out of 13 kittens, which was clinically and pathologically similar to infantile enteritis, by the oral administration of serologically labelled type A paracolon bacilli. Noting that the resistant animals were usually heavier than the susceptibles he performed another experiment on 24 kittens, to test the combined and separate effects of malnutrition and infection. 12 animals were deliberately under-fed and 12 were well-fed. Half the animals from each group were orally infected with paracolon bacilli type A, the remainder were uninfected. The well-fed, uninfected animals all remained well; five of the under-fed, infected animals contracted diarrhoea, three of whom died; only two of the well-fed infected group had diarrhoea (one death) and only one kitten from the under-fed non-infected group developed diarrhoea which was not fatal.

Dr. Sevitt pointed out the fallacy of drawing unwarranted conclusions from animal experiments on a small scale, but, nevertheless, the results did suggest that the previous nutritional state is important in determining how many among the infected will contract enteritis, and how many will escape. Arguing further, and possibly incorrectly, to man there is support for a dual conception of the aetiology of infantile diarrhoea, viz. malnutrition and infection, the former acting as the underlying and predisposing cause, the latter as the exciting agent. While he recognized that neonatal outbreaks in nurseries and maternity homes were apparent exceptions to this theory it was worth further investigation.

DISCUSSION ON SIMMONDS'S DISEASE. [Summary]

Professor H. L. Sheehan: NUTRITIONAL STATE IN SIMMONDS'S DISEASE.

The term "Simmonds's disease" will be used here to mean the clinical syndrome which results from a *long-standing and very severe* destructive lesion of the anterior pituitary. Such a lesion of the pituitary will be taken as the one essential feature of the disease, and the syndrome shown by patients with this lesion will be accepted as the true clinical syndrome of Simmonds's disease. The clinical diagnosis of Simmonds's disease in living patients should be based on this actual syndrome and on the specific evidence of the existence of the pathological lesion which can usually be obtained.

This interpretation is basically different from the two other common concepts of the disease:

(1) The usual definition of Simmonds's disease nowadays is that it is a syndrome identified by four cardinal characteristics: loss of weight, loss of sexual function, asthenia, low basal metabolic rate. This syndrome is usually accepted as clinical evidence of severe pituitary deficiency. In actual fact, however, as will be shown, most of the patients who have pathological proof of severe pituitary damage of long duration do not show all four characteristics of the syndrome; in particular, they rarely have a severe loss of weight. This definition is thus unsatisfactory.

(2) Certain authors maintain that the term "Simmonds's disease" should be confined to the syndrome, with its pathological basis, described by Simmonds in his original paper "On Disappearance of the Pituitary with Fatal Termination". Admirable though that paper is, it does not, however, give a perfect picture of what is now known about severe chronic hypopituitarism. Nevertheless it is of interest to note that Simmonds's patient (who was of medium height according to Leschke) had the quite passable weight of 103 lb. nine years after the onset of the disease. She died two years later. Simmonds mentioned that she was very thinned a few days before death, but he did not refer to loss of weight again.

In order to ascertain what is the actual syndrome which results from severe pituitary destruction of long standing, a detailed study has been made of the 103 published cases where post-mortem examination proved the existence of lesions of this type, whatever their aetiology. These can be accepted pathologically as incontrovertible cases of Simmonds's disease, and their clinical condition should therefore give a really reliable picture of the syndrome as it does, in fact, occur.

The state of nutrition of these patients *at the time of death* was as follows:

Fat	Good	Normal	Fair	Thin	Emaciated
9	11	36	19	14	14

These data are, however, of limited value. Simmonds's disease has commonly a duration of ten to thirty years. From the clinical aspect it is clearly more important to know the state of nutrition of the patients throughout the course of the disease than that of the corpses at the end of the terminal stage. (Some of the patients had died of wasting diseases such as tuberculosis, carcinoma, vomiting, &c.) For this reason a further assessment has been made of the nutritional state of the patients *at six months before death*. This appears to give a fairly representative picture of the nutrition throughout the prolonged course of the disease:

Fat	Good	Normal	Fair	Thin	Emaciated
9	11	57	11	9	6

These figures are obviously very different from the data of Escamilla and Lissner in

their Series A of "typical clinical cases of Simmonds's disease with pathological verification". The explanation lies in the different definition of Simmonds's disease; these authors adopt the second definition given at the beginning of this paper. A study of their 101 cases shows that 41 are acceptable as severe pituitary lesions of long duration; the remaining 60 cases showed lesions which were of only moderate or minor severity, so that they cannot be accepted as having produced significant hypopituitarism, or of such short duration that they cannot be accepted as having produced chronic hypopituitarism.

It is of interest to compare the present figures with those of 55 published reports of living patients with clinical evidence of very severe hypopituitarism of several years' duration following post-partum necrosis of the anterior pituitary. These patients had typical obstetric and clinical histories though, of course, there was no pathological verification of the lesions. Their state of nutrition was as follows:

Fat	Good	Normal	Fair	Thin	Emaciated
2	6	27	13	4	3

The present analysis has been restricted to severe lesions. From the study of 100 published cases of lesser degrees of pituitary damage proved by post-mortem examination, it appears that, if the remaining parenchyma is about one-quarter or one-third of the original gland, there is little or no pathological or clinical evidence of hypofunction. The survival of even one-eighth of the gland is often sufficient to prevent significant effects. The nutritional state of patients with lesser degrees of pituitary damage will not be discussed here except to note that the most emaciated patients usually have the most normal pituitaries.

All types of pathological lesions in the pituitary can produce various amounts of destruction of the gland. It should, however, be emphasized that pathological studies of the early and healed stages of post-partum necrosis show that this lesion is particularly liable to give rise to a very severe destruction of the gland. The clinical syndrome which results from this particular lesion is quite as complete as that caused by severe pituitary destruction from other causes. The fact that patients with this lesion are usually of normal nutrition must not be misinterpreted as an indication that they have a lesser degree of hypopituitarism; it is merely an indication that one of the hitherto-accepted standard clinical criteria of Simmonds's disease is not in accordance with the facts.

Dr. A. W. Spence: *Terminology.*

Simmonds's disease is variously referred to as Simmonds's cachexia, pituitary emaciation and panhypopituitarism, but the term is also used to describe lesser forms of hypopituitarism brought about by post-partum necrosis of the anterior pituitary, in which wasting is absent and only part of the endocrine system is affected. Simmonds (1914, 1916, 1918) in his original descriptions drew attention to the great loss of weight which may be associated with atrophy of the anterior lobe and for this reason called the condition "hypophyseal cachexia". Sheehan (1939) has shown that Simmonds's disease most frequently arises after a post-partum necrosis which is usually the result of collapse at delivery, but that more commonly incomplete forms of the syndrome develop after this incident. As a result of his observations he considers that the prevailing view that the fundamental symptom of Simmonds's disease is emaciation is erroneous. In my opinion if it is correct to apply the term Simmonds's disease to the milder manifestations of anterior pituitary insufficiency, as appears to be the custom in some circles, it is equally correct to apply the term to mild hypopituitarism caused by a lesion such as a tumour, since this was included by Simmonds as one of the causes of his syndrome. This, it will be generally agreed, would lead to confusion. I am of the opinion that if the term Simmonds's disease is used at all it should be applied only to those cases exhibiting manifestations of

panhypopituitarism brought about by an organic lesion, and not to those milder cases in which, for instance, the only feature of pituitary insufficiency is a disturbance of gonadal function. When more is known about the pathology and manifestations of a disease process, it is not always entirely satisfactory to describe the disease by a man's name, because cases may be included which clinically bear not the slightest resemblance to the original description. I think, therefore, that it would be more satisfactory to refer to Simmonds's disease and to the incomplete forms of the syndrome in terms of their pathology—post-partum necrosis, tumour, syphilis, &c.

Cachexia.—It has been doubted whether loss of weight is really directly due to a pituitary lesion and it has been suggested that any loss which may occur can be explained by a reduced intake of food. Experimentally it has been shown that removal of the pituitary causes cachexia and decrease of food intake and that injections of anterior pituitary extract cause an increase of food intake and of body-weight in the hypophysectomized animals (Smith, 1930; Richter and Wislocki, 1930). Clinically, in anterior lobe insufficiency loss of weight may occasionally precede loss of appetite. It is possible that the anterior lobe produces a hormone (? growth hormone) which is concerned with the maintenance of nutrition.

It has to be explained why many patients with post-partum necrosis do not lose weight and why some actually gain. Firstly, the degree of pituitary damage may not be sufficient to affect nutrition. Secondly, Smith (1926) has shown that injury to the tuber cinereum in animals results in adiposity. Since post-partum necrosis may sometimes damage the intermediate and posterior lobes causing polyuria, it is conceivable that it may also damage the tuber cinereum. The resulting tendency to increase in weight would counterbalance or more than counterbalance the tendency to lose weight that arises through damage to the anterior lobe.

Diagnosis.

The commonest cause of Simmonds's disease (panhypopituitarism) and of the incomplete forms is a post-partum necrosis. Apart from this, the disease is extremely rare and hence its diagnosis in men and in women who have not had a complicated delivery should be made with caution. The condition is diagnosed more often than it exists and on the other hand milder forms are overlooked. Dr. Russell Fraser will discuss the insulin sensitivity test and 17-ketosteroid excretion.

Myxœdema.—The clinical features of a post-partum necrosis may be confused with myxœdema, but although the basal metabolic rate may be as low as -40% , the facial appearance is not so heavy, the malar flush is absent, the skin is not so coarse and myxœdematous changes are rarely present. Primary thyroid myxœdema will not respond to injections of thyrotrophic hormone, whereas in hypothyroidism due to pituitary insufficiency the thyroid will respond to stimulation with thyrotrophic hormone and the basal metabolism will consequently rise. In doubtful cases this test is a useful adjunct to the insulin tolerance test and the estimation of the 17-ketosteroid excretion.

Anæmia.—Cases have been reported in which anæmia has been the predominant feature, but other evidence of pituitary insufficiency is usually present.

Wasting diseases.—The emaciation of Simmonds's disease must be differentiated from other wasting diseases and this may be difficult sometimes. Here again I would point out that unless the condition occurs in a woman with a previous history of a complicated delivery, the probability is that it is not a case of Simmonds's disease, but rather one of the commoner wasting diseases. Even if there is such a past history, one should be very careful to exclude a condition such as malignant disease.

Anorexia nervosa.—The disease *par excellence* which is confused with Simmonds's disease is anorexia nervosa. Continental writers in particular appear not to recognize anorexia nervosa as a clinical entity, but consider it to be a manifestation of hypopituitarism. Many of the cases reported as Simmonds's disease are typical examples

of anorexia nervosa. Admittedly the two conditions sometimes may be almost indistinguishable; even loss of sexual hair may occur in anorexia nervosa, but far less frequently than in Simmonds's disease; more usually there is a downy hirsuties. Lethargy and somnolence characterize Simmonds's disease, whereas patients with anorexia nervosa usually exhibit a surprising activity, but sometimes they may be lethargic. Differentiation rests mainly on the discovery of an initial psychological factor which is always present in anorexia nervosa.

As an argument against the view that anorexia nervosa is primarily a disturbance of the anterior pituitary, we cannot produce the statement that there is no evidence in the history of these patients that they had sustained any pituitary damage, because the protagonists speak of "functional Simmonds's disease" and "functional hypopituitarism". What refutes their hypothesis is that these patients get well with correct psychological management and without the administration of a single endocrine preparation.

I think that the existence of "functional Simmonds's disease" or "functional hypopituitarism" is possible. Since some cases of infantilism are probably due to a constitutional functional insufficiency of the anterior lobe occurring some time before puberty, a similar disturbance is not impossible after puberty. I wish to stress, however, that such a diagnosis should never be made before a disease such as anorexia nervosa has been carefully eliminated.

Dr. Russell Fraser: DIAGNOSIS.

The term "Simmonds's disease" should probably be used broadly for all syndromes having loss of sex function, muscular weakness and evidence of generalized atrophy, in association with a demonstrable pituitary lesion. This excludes pituitary hypogonadism, whether eunuchoidism or amenorrhœa without other defect, and pituitary dwarfism with no muscular weakness. It may be necessary to establish the clinical diagnosis by two or more metabolic tests which can demonstrate the relevant pituitary insufficiency. Preferably one should measure gonadotrophic and the other non-gonadotrophic anterior pituitary function.

The demonstration of non-gonadotrophic anterior pituitary insufficiency is achieved by the combined use of at least two of the following three types of indirect test:

(1) An intravenous insulin tolerance test. This test involves a stress (hypoglycæmia) antagonized by the anterior pituitary gland, and assesses its efficiency better than any other test of carbohydrate metabolism.

(2) A urinary steroid assay. This indicates the level of adrenal cortical activity: a determination of 17-ketosteroids is the simplest method but it is also affected by gonadal secretion in the male. Kepler's test of adrenal cortical function is probably not so sensitive or so specific in less severe cases of Simmonds's disease.

(3) A test of thyroid function. An estimation of basal metabolic rate, or of protein-bound plasma iodine is the best, but an E.C.G. or an estimation of serum cholesterol may suffice sometimes. The value of a test of thyroid activity can be enhanced by daily injections of thyrotrophic hormone, which cause a rapid improvement in thyroid function where the deficiency is not dependent on primary thyroid disease.

The diagnosis of Simmonds's disease can probably be confirmed when any pair, except (2) and (3), of the above three types of tests show typical abnormalities of pituitary insufficiency.

Susceptibility to hypoglycæmia and hypersensitivity to insulin are well recognized features of anterior pituitary deficiency, but the twelve-hour fasting blood-sugar level, or the glucose tolerance test, are insufficiently sensitive to recognize these abnormalities except in severe cases (Escamilla and Lissner, 1942). The combined insulin and glucose test of Himsworth is no more satisfactory in our experience, as might be expected, because impaired absorption of glucose is a characteristic of Simmonds's disease and it interferes with the usual interpretation of this test as a measure of insulin sensitivity.

An insulin-tolerance test was shown by Houssay and Magenta (1924) to give a characteristic response in hypophysectomized animals. This has been confirmed frequently by others and a standard procedure has been evolved for clinical use (Fraser *et al.*, 1941).

This intravenous insulin tolerance test has shown significant changes in a series of patients with relatively mild Simmonds's disease in whom a history of a pituitary lesion was probable because other characteristic metabolic changes were present, and there was a typical post-partum hæmorrhage and shock at the onset of the disease, or evidence of a pituitary tumour (Fraser *et al.*, 1941).

In such cases there is a normal rapid fall of blood-sugar to hypoglycæmic levels followed by an abnormally slow return to the fasting level. The blood-sugar curve, which is expressed as a percentage of the fasting level, reaches its trough (50% of fasting blood-sugar $\pm 10\%$) within half an hour, but does not return to within 10% of the fasting level in the next two hours. This is called *hypoglycæmia-unresponsiveness* and is the opposite of what occurs in the diabetic patient (fig. 1).

Fig. 1.—Insulin tolerance test curves from 10 patients with Simmonds's disease compared with the normal (see Fraser *et al.*, 1941, for case details).

The test is useful for distinguishing primary myxœdema, which gives a normal curve in mild cases, or an abnormally slow fall of blood sugar in severe ones; either result with a myxœdematous syndrome excludes anterior pituitary insufficiency. Patients with Addison's disease and hyperinsulinism show a similar abnormality to those with Simmonds's disease but they can generally be distinguished clinically. The test has been found to give a normal response in pituitary dwarfs without other evidence of pituitary insufficiency, in parapituitary diseases such as tumours compressing the hypothalamus without causing Simmonds's disease, and in uncomplicated primary or secondary gonadal defects. Severe hypoglycæmia should not occur with this test if certain precautions are observed (Fraser *et al.*, 1941). Any patients suspected of moderately severe pituitary deficiency should first be tested with one-third of the standard dose of insulin. If obvious mental confusion develops the test should be interrupted since this indicates abnormal hypoglycæmia-unresponsiveness. Meals should be given to all patients not less frequently than every three hours for the rest of the test-day. For approximately five days before the test patients should take a normal diet, including 250 to 350 grammes of carbohydrate per day. This is necessary for the correct interpretation of all carbohydrate tests. Severe general or liver diseases must also be excluded by clinical examination if abnormal hypoglycæmia-unresponsiveness is to be attributed to endocrine disease.

The urinary excretion of 17-ketosteroids is usually less than 2 mg. per twenty-four hours in Simmonds's disease (Fraser *et al.*, 1941), but a slightly higher level may be confirmatory in mild cases or when no correction has been made for non-specific colour formation. Similar very low levels of 17-ketosteroid output may also be encountered in severe liver disease, grossly defective intestinal absorption as in sprue, myxœdema and Addison's disease, and low levels, 2-5 mg. per twenty-four hours in women and 2-7 mg. in men, may be found in almost any case of general debility. The chief value of the test is to distinguish Simmonds's disease from anorexia nervosa and hyperinsulinism in both of which the response is usually about normal.

Dr. S. Leonard Simpson: TREATMENT.

These observations are based on a study of six patients with unequivocal post-partum necrosis of the pituitary gland, observed during the past ten years.

Hypophysectomy leads to involution or atrophy of the thyroid, adrenal cortex and gonads, and deprives the body of other essential anterior pituitary hormones, especially the diabetogenic and nitrogen retaining factors. Patients with pituitary insufficiency, therefore, should be treated with thyroid, adrenal and gonadal hormones directly, or these should be replaced indirectly by the trophic hormones which stimulate the glands to renewed activity. In either case the substitution therapy must be continued unless spontaneous recovery occurs.

Thyroid.—Thyroid extract is needed in doses sufficient to raise a low B.M.R. and depress the blood cholesterol to normal. It must be given in gradually increasing doses, because it is as poorly tolerated as in myxœdema, and a patient may become much worse long before the basal metabolic rate approaches the normal (e.g. -18%), the symptoms being those of anorexia, nausea, vomiting, abdominal pains, collapse and shock. These symptoms have been interpreted as being due to acute adrenal insufficiency (Means, Hertz and Lerman, 1940; Lerman and Stebbins, 1942), and thyroid is better tolerated by patients receiving saline or desoxycortone.

The scalp hair is somewhat improved, but the pubic and axillary hair do not return. The final result of thyroid treatment is poor even when the B.M.R. is raised to normal.

Thyrotrophic hormone was used by Bulger and Barr (1936) in one case; the B.M.R. was raised from -28% to -3% , there was an increased rate of nitrogen loss and creatinuria, the patient lost weight and developed pyrexia, nausea and asthenia.

Adrenal cortex.—The Kepler test for adrenal insufficiency was positive in all the four patients in this series in whom it was tried. In one it was negative at first but it was repeated six months later and found to be positive. In the remaining two cases it was not done. The delay in water excretion was more marked than the changes in chloride and urea concentrations in the blood and urine. Subnormal values for blood chloride and sodium were present in the more severe cases although none showed elevated potassium concentrations. The 17-ketosteroid excretion was low in four cases (0.6, 1.5, 2.8 and 3.2 mg. per twenty-four hours) and normal in one undoubted one (12.0 mg. per twenty-four hours).

The assays were done by W. W. Payne and M. Reiss and N. H. Callow.

Desoxycortone.—In Case I the injection of 2.5 mg. of desoxycortone every other day produced some improvement in strength, appetite and well-being, but 2.5 mg. daily caused œdema of legs and 5 mg. daily severe water retention. In Case III there was a moderate clinical improvement when 5 mg. of desoxycortone was injected daily and subsequently this was maintained by the implantation of 400 mg. of desoxycortone. The blood-pressure remained low, and the patient very depressed, however, until methyl testosterone was given by mouth. In Case V the injection of 5 mg. desoxycortone daily produced moderate clinical improvement, but the blood-pressure remained at 90/60 mm.Hg and the patient was easily fatigued. When the dose was increased to 10 mg. daily the patient felt ill and developed œdema of face and lungs and dilatation of the heart. The blood-pressure rose to 124/70 mm.Hg, the serum potassium fell from 20 to 15 mg. per 100 c.c. and the serum sodium rose from 314 to 327 and chloride from 547 to 600 mg. per 100 c.c. In the three patients on whom it was tried desoxycortone proved of moderate clinical value only, and there was a considerable danger of overdosage.

Pig adrenal cortical extract, containing relatively large amounts of the carbohydrate-regulating factor, is likely to be of greater benefit than desoxycortone or salt.

Adrenocorticotrophic hormone.—Adrenocorticotrophic hormone was tried in two cases and apparently it was of moderate clinical value in one, causing an increase in the amount of pubic and axillary hair. The patient appeared to become refractory after a few weeks and local reactions were severe. Hemphill and Reiss (1944) reported good results in a woman aged 39 in whom the urinary excretion of 17-ketosteroids rose from 2.6 to 8.3 mg. per twenty-four hours.

Testosterone.—It is now well established that the adrenal cortex secretes androgens, and adrenosterone has been isolated from it. This is the explanation of the low output of 17-ketosteroids usually found in Addison's disease and Simmonds's disease, especially in women. Does an absence or diminution of androgens cause symptoms and signs in Simmonds's disease? The answer is a definite affirmative, both on experimental and therapeutic evidence. Hypophysectomy leads to a negative nitrogen balance which can be corrected by testosterone. In 1938 I demonstrated an anabolic effect of testosterone in hyperthyroidism, although the thyrotoxicosis persisted. Some months ago I showed at this Society two cases of surgical hypophysectomy, in which testosterone had abolished severe asthenia and produced an increase in weight and strength (Simpson, 1947). Jones *et al.* (1941) demonstrated that testosterone in eunuchoids produces an increase of B.M.R., a retention of nitrogen, sodium, potassium, phosphorus and water, and a fall in respiratory quotient. (? metabolism of fat). Weiner and West (1943) showed that methyl testosterone by mouth in hypopituitarism produces a retention of nitrogen, an increase in B.M.R., a return of the glucose tolerance curve to normal, a decrease in blood cholesterol, creatinuria and an increase in weight and strength.

In all cases in the present series, testosterone or methyl testosterone caused an increase in appetite, weight, strength, libido and eroticism, and a psychological improvement. It also produced a return of the hair in the pubic region, axillæ and eyebrows, and a darkening of the hair of the head. Initially 50 mg. of testosterone injected daily appeared to produce unfavourable results with nausea, malaise and mental disturbance. A total of 150 mg. of testosterone a week proved to be the optimum dose by injection; or 15 to 30 mg. of methyl testosterone daily by mouth. An implantation of 400 to 600 mg. of testosterone was also effective, but there was often a latent period of several weeks during which the patient was unwell. Implanted tablets of testosterone are sometimes extruded. It is interesting that testosterone abolished the hot flushes which occurred in two patients because they are usually ascribed to hyperpituitarism or more specifically hypergonadotrophic secretion (Albright, 1936) and Sharpey-Schafer (1940) found that testosterone may produce hot flushes in men with enlarged prostates or with eunuchoidism.

The hypochromic or hyperchromic anæmias sometimes associated with Simmonds's disease may not respond to iron or liver therapy unless testosterone is given also (Watkinson, McMenevig and Evans, 1947).

Progesterone.—Beall isolated progesterone from the adrenal cortex in 1938, and Emery and Greco (1940) found progesterone as effective as desoxycortone in prolonging life and maintaining growth in adrenalectomized female rats. It seemed likely, therefore, that it might be of value, perhaps more scientific than pragmatic, in Simmonds's disease. I was much interested to find in Case I that an implantation of 6 tablets of 50 mg. of progesterone, 5 of which were retained completely, produced a similar systemic effect to that of testosterone and caused growth of the hair on the pubic region, axillæ and eyebrows. Another patient, Case VI, has had a recovery of pubic and axillary hair-growth which had also failed to respond to œstrogen and thyroid therapy previously. Experimentally, progesterone has only a slight androgenic effect on mammals (Emmens and Parkes, 1939; Greene, Burrill and Thomson, 1940), but a definite effect on fishes (Eversol, 1941), and desoxycortone has a progesterone-like effect on monkeys (Zuckerman, 1940).

Estrogens.—Treatment with œstrogens causes some clinical improvement, but not as great as androgen therapy. The scalp hair increases in abundance, lustre and colour but the pubic and axillary hair do not recover, although in one case the eyebrow hair appeared to grow again.

Gonadotrophins.—Lerman and Stebbins (1942) found in one case of Simmonds's disease that 20 units of pregnant-mare's serum injected daily changed an inactive endometrium to a proliferative one, and produced libido, menstruation, better hair-growth on the scalp and eyebrows, and an increase in strength. Bécère and Simonnet (1946) found that patients with post-partum pituitary necrosis may have a failure of gonadotrophic secretion only with amenorrhœa, and they respond to a mixture of pituitary and chorionic gonadotrophins. The latter was tried in one patient only, Case I, and caused a dramatic allergic reaction which led to collapse and nearly proved fatal.

The treatment of hypoglycæmia.—Hypoglycæmia may be responsible for the peculiarities of behaviour and psychotic symptoms in Simmonds's disease, and it may cause death, as in one patient, Case II, who had repeated attacks of spontaneous hypoglycæmic coma. Lipoid extract of adrenal cortex (Upjohn), which is not yet available in quantity in this country, should be of value in this condition, although the injection of 15 c.c. in divided doses prior to the insulin-sensitivity test in one case did not restore the sensitivity to normal. It had a more marked effect, however, on the insulin-sensitivity curve in Addison's disease. It is probable that the pituitary diabetogenic and anti-insulin hormones are more important in preventing hypoglycæmia in Simmonds's disease.

Dr. C. N. Armstrong mentioned a case of Simmonds's disease in a lady aged 49, diagnosed in 1936 by the late Sir Walter Langdon-Brown. Her illness had had an insidious onset over the previous two years and had not followed parturition. Radiological examination later showed the pituitary fossa was enlarged and there were calcified bodies in the enlarged pituitary gland. When seen by Dr. Armstrong in 1945 her health had deteriorated, and she had developed pulmonary complications. She was treated with corticotrophic hormone, and the following day her appetite returned. She continued to improve, her chest condition cleared up, and she began to put on weight. It was found that if corticotrophic hormone was discontinued for longer than two weeks she relapsed, and improved immediately treatment was resumed. The subsequent regime of treatment consisted of 10 units daily of Cortrophin (Organon), every alternate two weeks. On this routine her appetite was maintained, she enjoyed her food, and general improvement was upheld.

He mentioned another case which supported the remarks of previous speakers that oestrogens improved the condition of hair on the head in Simmonds's disease. A man whose hair had receded at the temples in a normal male manner developed feminism and subsequently his hair grew in a straight frontal line of feminine type. Thus it appears probable that oestrogens are responsible for the hair on the head and androgens for axillary and pubic hair.

Thyrotoxicosis in Mother with Cretinism in Child.—K. P. BALL, M.D., M.R.C.P., and BRENDA MORRISON, M.D.

Mrs. E. L., married woman, aged 32, had had a goitre for five years. She had never lived in an endemic goitre area and there was no family history of thyroid disorder. During her second pregnancy in 1946, she noticed increasing tiredness and sweating. Following childbirth, these symptoms became much more marked, her appetite increased, she lost weight and her goitre became larger.

June 1947: She attended the Central Middlesex County Hospital, where thyrotoxicosis was diagnosed. Basal metabolic rate + 47%. She was treated with methyl thiouracil, 600 mg. daily for three weeks, then 100 mg. daily with some improvement.

August 1947: She stopped treatment owing to headaches, and later she developed pneumonia and was treated at home.

December 1947: She was admitted to hospital with a relapse of thyrotoxicosis.

Basal metabolic rate + 60%. She was again treated with methyl thiouracil and has done well, gaining nearly one stone in weight.

Pamela L., born 29.1.47. Soon after her birth, her mother noticed that she would not take to the breast and failed to gain weight. She had a big tongue, a dry skin and an umbilical hernia. She was bottle fed after one month, but still would not take her feeds. At ten weeks she weighed 8 lb. 10 oz. Aged 3 months: Attended Great Ormond Street Hospital, where it was noted that she was a mouth breather, had a dry coarse skin and had a very large umbilical hernia. Blood cholesterol 162 mg. per 100 ml. Probable cretinism was diagnosed. She was treated with thyroid, gr. 1/8 b.d. and within a week she took her feeds normally and began to gain weight and became more lively. She continued to improve until aged 9 months. Treatment was stopped when mother became ill. At 11½ months she had no teeth, her anterior fontanelle was large and she had the appearance of a cretin. Blood cholesterol 298 mg. per 100 ml. She was treated with thyroid, gr. 1/4 daily, and has again improved.

Adrenal Virilism (Group I). Bilateral Partial Adrenalectomy.—A. ELTON, F.R.C.S. (for L. R. BROSTER, O.B.E., M.Ch.).

Kay H., aged 9½ years.

September 1946: The case was sent up as a pseudohermaphrodite.

On examination.—Speech distinct, voice female; normal intelligence; legs boyish; markedly hypertrophied clitoris with urethra opening below this, enlarged prepuce, no scrotum, small vestibule, no vagina; pubic hair of female distribution (fig. 1). Marked muscular development. Blood-pressure 120/80. *Rectal examination:* small indefinite structure felt. ? infantile uterus and vagina. Urine—no abnormality.

X-rays: Epiphyses compatible with age 10 to 12 years; skull, no abnormality; adrenals, no calcification. Urinary 17-ketosteroids 44 mg. per day. Sugar tolerance curve normal. Diagnosis was then made of Group I adrenal virilism.

7.2.47: Laparotomy (L.R.B.). Both adrenals found to be four to five times normal size. Very small infantile uterus present. Both ovaries showed follicular cysts. A section was taken of each and showed normal ovarian tissue.

21.2.47: Right partial adrenalectomy, removing two-fifths of the adrenal; the part removed weighed 7 grammes.

4.3.47: 17-ketosteroids 12.1 mg. per day.

10.12.47: Seen again. Hypertrophied clitoris, some enlargement of breast tissue. 17-ketosteroids 26.2 mg. per day.

10.1.48: Left partial adrenalectomy. Left adrenal found to be five times the normal size and two-fifths of it were removed. Remains of right adrenal palpated and found intact.

Convalescence was uneventful. Present

17-ketosteroids 22 mg. per day.

Sub-total adrenalectomy for Group I Virilism.

Dr. Russell Fraser thought that bilateral partial adrenalectomy was particularly dangerous in this condition because of the reports of pseudohermaphrodites with adrenal cortical hyperplasia dying of Addison's disease.

Dr. A. C. Crooke said that a number of such cases had been reported now but adrenal cortical insufficiency with adrenal cortical hyperplasia and pseudohermaphroditism had so far only been described in infants and very young children and he thought that it was clear from the alternative that the only hope of relieving pseudohermaphroditism in patients like Mr. Elton's was bilateral adrenalectomy.

DISCUSSION: JUVENILE DELINQUENCY WITH SPECIAL REFERENCE TO REMAND HOMES

Professor Alexander Kennedy, (University of Durham):

Dis proximus ille
Quem ratio, non ira movet, qui facta rependens
Consilio punire potest.—Claudianus.

Few will deny that since the Children's Charter of 1908 the attitude of the Law and of public opinion towards the juvenile delinquent has become more liberal, humane and farsighted. Since that bloodless revolution in legal procedure the courts have by degrees transferred their interest from the nature of the offence to the nature of the offender and his circumstances. There has been since then an increasing recognition of the fact that in some cases punishment, so far from failing to deter the child from further antisocial behaviour, may sometimes even destroy his faith in society and foment his inward rebellion against its laws. The Act of 1908 gave expression for the first time in statutory terms to the view that the juvenile offender might be more sinned against than sinning and that the cause and the cure of his condition might emerge from an investigation of his background, which was and still is often one of poverty, of ignorance, of lack of outlet for normal energy or of disease and neglect.

In this important reform Psychiatry played no part, nor at that time had it much to contribute to the problem. The exposition of the psychopathology of juvenile delinquency in the novels of Dickens is far in advance of anything that psychiatrists could have written at the time. The position to-day is different and though great progress has yet to be made Psychological Medicine can contribute a great deal in certain types of case provided that the limitations of our present knowledge are fully realized.

The period between the Act of 1908 and the Children and Young Persons Act of 1933 was one of very uneven progress. In many areas there was little change in the attitude of magistrates, whose experience and interest were in any case with the adult offender and the Penal Code. Those who were interested in children, however, and in their social problems and in the prevention of adult crime began to realize the magnitude of their new responsibilities and the complexity and infinite variety of the factors of constitution and circumstance which were at work in the children who appeared before them only for a few brief minutes. They began to appreciate that each child presented a human problem the solution of which required infinite patience and kindness and no little specialized knowledge.

Some found it difficult to forsake the traditional impersonality of the Law and continued to make the punishment fit what they looked upon as the crime. They regarded with suspicion any tendency to lack of firmness in dealing with the young. Such an attitude is of course economical of time and of thought and it has its advocates even to-day. Only this year, however, has the Law removed from their hands the birch which reason and experience could not bring them to lay down. If he is to do justice to the children to whom he will be so important a memory, the juvenile court magistrate must go much further than mere interpretation of the Law and must now bring to his aid some of the method of science, the method of patient gathering of the facts, comparing them with previous facts, taking action only after careful consideration, observing the results and applying them to later cases.

It was logical that those who accepted these new responsibilities should invite scientific workers to assist the courts and the results of this co-operation were important. General recognition of the importance of mental defect and backwardness was perhaps the first important effect. The defective is not often punished for his stupidity nowadays but if we take a wide view of mental defect and do not confine it to intellectual defect as revealed by tests of intelligence we have still much to learn in this field. One of the after-effects of the outbreak of sleepy sickness in the '20s was to bring recognition of the influence of that disease on the power of ethical valuation in its victims and to draw attention to disease of the nervous system as a predisposing cause of antisocial behaviour. Here again the possibilities have by no means been fully explored. In the same way the application of the principles of psychopathology showed that disorders of behaviour could be the expression of emotional disturbance and that in some cases treatment based on this might have favourable results. This approach has fundamentally altered our attitude to the subject even though we now realize that full psychological treatment is indicated only in a minority of cases and that an excessive enthusiasm in this direction is not without its dangers. Lines of investigation such as these showed clearly enough that in many cases more detailed study of the children was necessary than could be done under existing arrangements, and the work of Clarke Hall, Burt and others pointed the way to the next step. The act of 1933 secured for the courts a framework of procedure within which they could, where necessary, find all the technical assistance they wanted. The court's decision was by now beginning to be more and more like a diagnosis, with a prescription for the treatment of the young offender.

Since 1933 there has been much trial and some error but in some areas great progress has been made. It is generally agreed that we have not yet got the best out of the Children and Young Persons Act, and in the matter of making the best use of specialized facilities for investigation, treatment and training there is still a long way to go. As more reforms come into effect, such as those contained in the Criminal Justice Bill, the need for a fuller understanding between the courts and their technical advisers becomes more urgent, and among those who assist the courts the psychiatrist occupies a unique position.

A psychiatrist is in a somewhat different position from the other specialists who assist the court in that he has been trained or should have been trained to make use of a team of investigators and to know enough of the work of each of them to assess its relevance to the case. He is better aware than the others of the possible pathological variations which may be found in the child and, as a rule, concentrates his own examination on the most difficult part of the investigation—on the child's attitude of mind and the mental dynamics of his behaviour. His more general review of the difficult case acts as a safeguard lest anything has been missed and in the statutory, medical and school reports there is no doubt that things frequently are missed. The psychiatrist's part therefore in ideal circumstances is to present to the court concisely and in plain language a living picture of the child's mental state with its potentialities and deficiencies, of the personal and social difficulties with which he is faced and of the probable reasons for his present conduct and attitude to life. He must also make definite suggestions for the child's future which are practicable in the light of existing facilities. The magistrate is then able to base his decision on a consideration of this report, upon his own observations and on the evidence.

In practice this system works fairly well in those courts where the magistrate and psychiatrist are both experienced and where they have worked together long enough to understand each other's limitations and where each realizes that every case is an experiment, the results of which must be carefully observed. A good deal of misunderstanding does arise, however, and the causes of this are worthy of review.

In the first place many magistrates who are baffled by a child's behaviour are apt to lean too heavily on the specialist and do not realize that he cannot be right every time. This may be the fault of the psychiatrist who is over-confident of his interpretation of the cases he sees but the inexperienced magistrate who finds him proven wrong by the child's appearance

in court again may lose faith in all psychiatrists and may tell his favourite psychiatrist story to all his friends. There are, of course, magistrate stories as well. If there are many inexperienced magistrates, the shortage of psychiatrists with sufficient training and experience to give the highest standard of service to the courts is even greater. Training in this branch of the subject has only very recently become part of the normal training of a psychiatric consultant. It is fair to say, too, that a psychiatrist cannot know enough about the background of juvenile delinquency until he has spent at least a year or so in examining cases and has had some contact with each of the many agencies concerned with the welfare of children; until he has done so his reports may reveal lack of knowledge of procedure, of the rules of evidence or of the facilities of disposal available for children. His theoretical training in psychiatry, too, needs very great modification when it is applied to this highly practical subject.

Magistrates are quite frequently irritated by the reports of psychiatrists in the early stages of their experience and there are some types of report which must be particularly irritating. Among these are the reports in which the psychiatrist recommends an entirely Utopian treatment, completely impracticable in the present state of organization of our children's services, or worse, implies that this treatment would cure the child but as it is not likely to be available, he washes his hands of the matter. Reports in which the psychiatrist defames the parents on the strength of hearsay evidence are, to say the least, embarrassing to the magistrate who wishes to read them out when the parents are present. Long-winded reports in which the magistrate seeks in vain for a clear-cut recommendation are of little practical value. Perhaps more serious are those in which the psychiatrist has paid scant attention to factors which the court realizes are important and has forced the case into a mould of psychopathological theory of one kind or another. Finally, magistrates may suspect, with reason in some cases, that technical verbiage may be hiding lack of experience or unwillingness to admit defeat. It is probably a sound principle both in Law and Psychiatry where there is so much technical language, that any view which cannot be put into plain English is quite likely not to be a sound one.

Perhaps the most important potential source of misunderstanding between magistrate and psychiatrist lies in the fundamentally different attitude of court and medical profession towards any defendant. A court is by constitution the protector of society whereas the doctor is by habit the protector of his patient and in the adult court he is frequently, perhaps too frequently, called upon to explain away his patient's behaviour. In the juvenile court his function is different; he is an impartial adviser, an excellent position for an expert witness which may, one day, be adopted in the adult courts. At the moment this position may call for some adaptation on the part of the psychiatrist if he is to strike a fair balance between his responsibility to society as well as to his patient. A similar effort of adaptation may be called for from the magistrate whose function in the juvenile courts includes that of protector of the child's interests.

The suggestion has often been made that the procedure of the juvenile court is too cumbersome and awe-inspiring to provide the sympathy necessary for dealing with children and that it might be replaced, as has been done in the Scandinavian countries, by a council of experts and social workers. In the United States, too, the juvenile court is a chancery and not a criminal court and it is my experience that technical evidence is accepted with far too little question in some American courts. In this country where the tradition of impartiality and fair trial is so strong I think we must regard with suspicion any tendency to substitute the technocracy of the child guidance clinic for the very democratic procedure of the courts. In particular I think we must preserve the principle that the individual may refuse investigations until it has been proved that an offence has been committed. The child should retain some rights as a citizen and contact with the dignity of the Law, suitably modified, is likely to do him no harm. It should be possible within our present system to arrive at a combination of British justice with an approach to the child which is both scientific and human.

The incidence of offences in general diminishes with age. It reaches a peak about the age of 13, when 13½ per 1,000 boys are found guilty in the course of a year, and falls rapidly as maturity is reached. Working with such material in which, in normal times, 70% of cases do not appear again after their first offence, in which over 70% of the lads sent to approved schools are not caught again within three years, it is easy to claim successful results for any method and apparent statistical success can be demonstrated for methods varying from the eye for an eye and tooth for a tooth theory to that curious religion to which some social workers appear to subscribe in which God is love and Sigmund Freud is his prophet, a faith which seems to have been a side-product of the development of psycho-analysis as we know it to-day. That such sophistries should be possible is a danger and one which can only be

averted by close follow-up of cases and by bringing home the results to those who have made the recommendations. The standard of not getting caught is hardly a test of citizenship and many of our apparent successes have merely learned to subvert the social order in some other way. The need for follow-up investigations on an entirely different scale to present methods is absolutely vital. No single factor can do more than careful follow-up to produce the humility in both magistrate and doctor with which both should approach their work.

Those who work with delinquent children are sometimes apt to think that the effect of the psychiatrist's examination is to make the case much more complicated and that probation officers or psychologists see the case in simpler terms. This would be an excellent reason for dispensing with the psychiatrist altogether were it not for the fact that human beings are very complex organisms and the more one learns to look for things in them the more one will find. This is particularly important in the case of children with constitutional abnormalities where early detection, while requiring the greatest experience and clinical acumen, is especially important owing to their potentiality for corrupting others. The children we see come for the most part from underprivileged homes but there are among them many whose handicap is neither material nor physical nor intellectual. It consists of a constitutional disability which comes gradually to light as their character develops and shows itself in an inability to march in step with their fellows, to form normal judgments and to feel a normal urge to conform to the rules of the community in which they live. In some cases this disability may be associated with abnormalities of the central nervous structure while in others these are not evident. As these individuals develop and fail to adapt themselves to living with other people the nature of the defect is revealed. Many of them merely suffer from their handicap but there are psychopathic personalities whose appearance in juvenile courts is the first sign of a condition from which society will be the major sufferer as they graduate from probation to approved school, from approved school to Borstal; from Borstal to prison and from prison to recidivism. Some of these can be helped if they are helped early enough, while for others society has not yet found a satisfactory remedy. That they should be recognized early and that their development should be under experienced observation and control is a necessity. At the moment cases of this kind reach the psychiatrist often only after they have upset the life of a remand home or an approved school, after they have stirred up trouble among their elders and in some cases after a variety of officials with strong views on treatment have accused each other of mishandling the case. More of these would undoubtedly be certified under the Mental Deficiency Act had not the assessment of mental deficiency so unfortunately become chained to the intelligence quotient in the minds of those whose duty it is to carry it out.

This group of rather depressing cases has been mentioned first in order to emphasize their importance at a time when the psychodynamic origin of behaviour disorder receives perhaps a disproportionate emphasis. It is fortunate that those in whom juvenile delinquency is a symptom of emotional disturbance are a larger group—children whose attitude and development have been stunted by emotional adversity and who need psychological protection, psychological first-aid or psychological treatment before they can stand alone among their more fortunate contemporaries. Many of these need protection only until the recuperative power of Nature, which is at least as evident in the field of mind as in physical medicine, has done its work. The dangers of over-treatment are considerable and it may often be enough simply to create the conditions necessary for natural recovery.

It has been suggested by experienced magistrates that every child who appears before the court should be the subject of a full investigation including a psychiatric examination. While no harm whatever can result from this in the hands of experienced workers the time and expense involved and the shortage of suitable qualified personnel make it almost impossible at the moment. The magistrates must thus be left to select those children in whose case they think investigation may lead to a better understanding and a practical improvement in disposal. We all know that cases of gross psychopathy, of nervous disease and of mental defect are sometimes referred for investigation only after their second or third appearance in court and the number of such cases to be found in approved schools bears witness to the frequency with which they are missed in court. When they are missed time is wasted and they are left free to corrupt other children in the streets. Dr. Scott has reported on an investigation which throws some light on the effectiveness of this selection in the hands of a group of experienced magistrates. As a result of this investigation it seems probable that their judgment should be assisted, except in trivial cases, by some sort of screening procedure. Such an examination, which could be made available both to cases remanded in custody and to children on bail or even on probation, might consist of a day spent at an observation centre during which group-tests could be given and play observed by experienced workers. If cases requiring further investigation were selected and added to those chosen by the court, it

might lead to earlier examination of those in need of specialized treatment and a greater possibility of rehabilitation before committal to an approved school becomes the only solution.

The selection of cases for detailed observation should, I think, be only one function of a centre of this kind. Some sort of clearing-house, in which information can be exchanged between those who are immediately concerned with a case, is badly needed—some means of ensuring continuity of investigation, treatment and subsequent follow-up. At present, if the court wish to carry out any special kind of investigation or if the case justifies a disposal or treatment which is out of the ordinary, considerable administrative difficulties may have to be overcome. In some areas the official machinery for dealing with delinquents has grown by accretion rather than by design and is cumbersome in operation. When the court has decided what is best for the child, the matter may pass into the hands of officials to whom the case is a paper transaction and whose interest in it is limited strictly to their hours of work and the failure of human material to fit itself into existing schemes for its disposal is a constant source of irritation to the less enlightened among them. It is a pity that the services of voluntary organizations have to be used so extensively to provide the individual attention and latitude which are needed in dealing with the young child and the first offender, and it is clear that in time all the facilities necessary for dealing with juvenile delinquents will have to be provided as part of the public service. The case for a central clearing-house combining the functions of observation centre, psychiatric clinic, social service exchange, record centre and treatment centre must be a strong one. In another place (*J. Ment. Sci.* 1948, In the press) I have set down the possible structure and functions of such centres which I believe should exist in a number of areas. They should be able to deal with cases in custody as well as with those coming up from their homes and treatment could be carried out on parents and children by the same unit who first found it to be necessary without the delay between diagnosis and treatment which at present so often reduces its value. Relatively few children need prolonged psychological treatment in my opinion but there are many who require a sort of psychological first-aid which must be given at the opportune moment. The opportunity afforded by the concentration of skilled personnel together with records and cases under treatment would provide an excellent background for the training of the many different types of specialist concerned with the young delinquent—among them the magistrate and the psychiatrist. In a number of parts of the world, centres of this kind already exist though in some cases their value is much reduced by a limited approach to the subject and adherence to one school of psychological thought. Enough has been learned from their efforts, however, for centres to be planned within the public service which would include their best features.

Our concern at the moment is almost solely with the child found to be delinquent. It is important that we remember that the offender who has not been caught is an even greater challenge. Although we may succeed with any one child who is brought before the court we are still powerless to prevent his younger brother from appearing as soon as he is old enough. We are often unable to prevent the potentially healthy but underprivileged child from passing his most impressionable years in a medium in which indifferent heredities breed in squalor and without healthy ideals of citizenship. A child's appearance in court is often only the presenting symptom of a malady, a defect of social adaptation which is afflicting his whole family or neighbourhood. A preventive outlook must be maintained even though the means at present at our disposal are greatly in need of further development. Nor would such an attitude be very new in relation to rebellion against the social order.

Χρή δὲ τοὺς ἐλευθέρους οὐκ ἀφισταμένους σφόδρα
κολάζειν ἀλλὰ πρὶν ἀποστήναι σφόδρα φυλάσσειν καὶ
προκαταλαμβάνειν ὅπως μὴδ' ἐς ἐπίνουαν τούτου ἴωσι.
(THUCYDIDES III, XLVI.)

Dr. P. D. Scott: The average annual number of cases brought before the London Juvenile Courts for the years 1940 to 1946 was 5,200, while the highest number remanded in any one of these years for the purpose of obtaining a psychiatrist's report was 630. The proportion of cases examined by the psychiatrist is thus a very small one and it may be of interest to investigate the criteria by which this proportion is chosen.

It is apparent that there are varying opinions as to the necessity for the psychiatrist's so-called "special report".

Vick and Curtis write "we gather that psychological reports are asked for rather freely—we are not altogether satisfied that they are not asked for too freely". Elkin on the

other hand writes: "It is impossible to visit many courts without becoming acutely conscious how great is the need for a wide extension of the facilities for medical and psychological examination." Cyril Burt was in favour of the examination of all but the trivial cases, remarking that otherwise the most hopeful cases may be passed by. He showed that 62% of cases where his recommendations were carried out appeared to be cured as compared to 12% where his recommendations were not carried out.

Hamblin Smith, referring to young offenders, said, "Every case requires individual investigation and consideration", and John Watson, "The ideal arrangement would of course be for the court to receive a medical report upon every child; . . . it is quite wrong that a bench of laymen should be charged, as at present, with the responsibility of making a 'spot' diagnosis of the cases which should be referred to the psychiatrist".

The consensus of opinion would therefore seem to be that ideally all but the trivial cases should be examined psychologically but that this at present is impossible. Reforms such as the setting up of remand centres may enable a greater proportion to be examined but even so the practical criteria for selecting cases for "special" reports will still be a problem.

Concerning this selection, Clarke Hall wrote: "No one without medical knowledge and experience can in all cases diagnose the necessity for a special report. Many children who may seem to a magistrate quite normal are in reality in very urgent need of such an investigation. . . ."

According to Elkin "it is only when a child is clearly unstable or presents obvious problems of behaviour that a request is made for a psychologist's report. But the effects of emotional stresses and conflicts are not necessarily obvious at first sight".

John Watson gives his opinion that, until better arrangements can be made, all cases of certain types should be referred as a matter of course—offences of a sexual nature, apparently motiveless offences and "peculiar" offences by which he is understood to mean those which one could not imagine an ordinary, mischievous child doing.

In an attempt to throw some light on this problem I examined 25 boys who had been sent to the remand home for purposes other than a special report, and compared them with 100 boys on whom I had been requested to make such a report. I shall refer to these as the non-referred group and the referred group. The selection was random except that in the non-referred group, cases upon which a previous psychiatric report had been made were rejected. Both groups were submitted to what I regard as the minimum adequate investigation. This consists of a physical examination, a psychometric examination, and at least two interviews with the child; the parents were requested to attend in every case and did so in 66% of cases and the reports of school officials, welfare and probation officers were studied. The object was to obtain as clear a picture as possible of the child and his setting, the family history, the development and present difficulties whether in the physical, social or emotional spheres, and to relate these difficulties (as well as the particular offence) to the total life of the child, thus determining their significance and appropriate treatment.

First as regards the charges: Table I shows a comparison of the charges in the referred and non-referred groups. The types of presenting symptoms which from the psychiatric point of view seem most strongly to indicate a need for full investigation are set out. These may be of practical use in a busy court-room. We may then compare these criteria with those evidently used by the magistrates.

(1) Stealing from the home is often found to be an act of aggression against the parents based upon unformulated feelings of deprivation and need for approval. The usual, and from our point of view most significant stealings, are those in which the child has taken the most cherished possession of a parent. I have for example four records in which the child stole his father's war medals, in other cases mother's clothing coupons, butter ration, and in one case a silver-framed photograph of a younger brother. It will be significant if the stolen goods have not been enjoyed at all but rather, as is usually the case, quickly thrown or given away or buried in the garden, or if they have been objects of which he could not possibly make any use. It is worth noting if the theft was precipitated by any particular incident and the emotional state of the child at the time. It is remarkable how little these emotionally determined delinquencies resemble the mischievous pranks of secure children. One boy of 10, less intelligent and successful than his sister, was given a lecture by his parents upon his poor school report. He went to his room and wept and then, when they had gone out, came down, stole the coal money, and dropped it down the drain in the road.

(2) Fire setting, wilful damage to property at home or elsewhere and what is referred to

in the courts as "grievous bodily harm" are overt aggressive acts which may be organically determined but more often have a similar motivation to the stealings already dealt with. They are mentioned here because it is felt that these highly antisocial acts and the intensity of aggressiveness displayed may arouse emotional reactions in those responsible for law and order thus possibly leading to summary punishment with forgetfulness of possible underlying psychopathology.

(3) Repeated lying, particularly of self-aggrandisement, or of accusations against the parents, usually indicates a need for investigation. One small boy who had been long evacuated returned to parents who no longer wanted him. He was physically well provided for and his management was outwardly correct but he persistently evoked the pity and pennies of strangers with stories of atrocities in his home, and reported himself at several police stations.

(4) Cases of wandering and persistently coming home late very commonly are due to remediable unhappiness of the child in the home and this is particularly likely to be the case if it is found that school conduct is relatively good.

(5) Persistent truancy is often associated with backwardness which leads to failure and discouragement at school and the natural wish to avoid such unpleasantness. Backward children are also likely to be less able to resist the lead of other boys in school who are truancy for other reasons and wish to bolster their courage by being accompanied. Psychometric examination may prove to be the most revealing part of their examination, but there are other truanters of good intelligence who show disturbances in other spheres dependent for example upon over-protection or, at the other end of the scale, neglect by their parents.

(6) Sex offences, though commonly discovered during the investigation are rare as presenting symptoms and always merit investigation. They seem to inspire a marked reaction particularly in parents and school teachers and are in no danger of being overlooked.

(7) Cases in which the disposal may possibly involve separation from home or change of foster home. Large among these will be the "Beyond control" and "in need of care or protection" cases which, I believe, should be referred unreservedly.

(8) Any repeated charge, or breach of probation would seem to merit investigation as indicating a failure of ordinary methods and a possible deeper significance.

(9) Young offenders should readily be referred for in them diagnosis is easier and the chances of successful treatment greater. The young child is also less likely to require remand in custody. The boy or girl of 16-17 may present a palimpsest of factors, many of them secondary effects of long delinquency. Unlike the younger children they may come to enjoy certain aspects of their delinquency and may have acquired a knowledge of the ropes and deeply ingrained attitudes and responses difficult to eradicate.

It will be noted that many of these indications fall within John Watson's groups—the sex cases, motiveless and "peculiar" offences.

Table I shows that all cases of stealing from parents, "grievous bodily harm", sex offences,

TABLE I.—REASONS FOR APPEARANCE IN COURT

Total number	Referred	Non-referred
	100 Actual no.	25 × by 4 for comparison

It is remarkable how little these emotionally determined delinquencies resemble the mischievous pranks of secure children. One boy of 10, less intelligent and successful than his sister, was given a lecture by his parents upon his poor school report. He went to his room and wept and then, when they had gone out, came down, stole the coal money, and dropped it down the drain in the road.

(2) Fire setting, wilful damage to property at home or elsewhere and what is referred to

It is clear to anyone who knows the difficulties which delinquent children offer, that it is impossible to recognize all the cases in need of special investigation and treatment unless all are examined fully as a routine. The following two cases are examples from the non-referred group.

CASE I.—A boy of 12 years, brought to court by his parents as beyond their control because he habitually stole from shops, truanted from school, stayed out late, was insolent and bad mannered.

A psychiatrist's report was not asked for. He was sent to the remand home pending the selection of a foster home.

Family history.—Father was a caretaker—steady man earning a regular wage. Mother was at home. She was an anxious, easily flustered woman, worn out by the constant moves from house to house which circumstances had imposed upon her. The boy was the youngest of five children each of whom had at one time or another presented a social or psychiatric problem. The home conditions and atmosphere were reported to be very bad.

Personal history.—As a little boy of 4 or 5, he had had *grand-mal* attacks, violent tempers, had broken windows in his rage and run his head against the wall. He was evacuated to the country, without his mother, and improved. At 8, he returned and his fits increased in frequency. He was admitted to a colony for epileptics, was reclaimed for a while by his mother but had to return. He was again taken out, against advice, and after several moves remained at home for a year before being brought to court. Major fits were occurring in groups at intervals of a few months. He was having no medicine. He had had no other illness or injury.

The school reported him as intelligent but intolerably insolent and unbearable in an ordinary school. On examination he showed no neurological signs and was well developed and well nourished. He had a habit spasm of his mouth and his nails were chewed down. He was shy, restless and tense, and it was difficult to gain his confidence. Even so his I.Q. (Binet) was 109. At a second interview he relaxed, and showed a photograph of his mother which he always carried round with him. "I would rather have 5 letters from her than 10 parcels" he said (children in the remand home are allowed parcels of fruit and sweets, but he had not received any), he told how he thought one of his sisters hated him and tormented him. Sometimes he felt an excited feeling inside him and then had to hold himself stiff, squeezing his arms against his sides. "When I leave you I shall have to go over everything I've said, I wish I could get out of it". He felt he had to touch certain things and count things on the table. In the Underground "something inside me says 'Jump on the line'". He indulged in many obsessional rituals.

The boarding-out officer was interviewed and found to be discouraged at having to find a foster home for this boy.

It was felt that he was at present incapable of settling either in his own or a foster home, that he needed treatment in a special residential school, and regular medication. His home offered a social problem upon which much work needed to be done if he was ever to return to it.

CASE II.—A boy aged 14½ had been brought to court three months previously as beyond the control of his mother. He had been placed under supervision of a probation officer who now brought him back because he refused to go to work. He had already been committed to an approved school when in the remand home. The father died when the boy was 5½. His mother was a hard-working, well-intentioned woman who had done her best for the boy. There was no history of nervous or mental disorder in the family. There was one other sibling, a boy, now settling well in the Army after presenting a very similar but less intense problem to this one. The mother said that he had been bottle fed, and had been cross and difficult as a baby. When he was between 2 and 5½ years she had been fully occupied looking after her husband in his long illness. The boy was a bed-wetter and got on his mother's nerves because he was "always wanting help with everything". He cried a lot when he had to go to school. At 6, he was evacuated, without his mother, for three years.

The real trouble started when he returned home. He was indolent and disinterested, took no notice of his mother, though he infuriated her with his careless ways and bed-wetting. At school he showed the same indolence and truanted regularly. Since leaving he had tried several jobs but showed no enthusiasm. He failed to attend the clubs to which the probation officer introduced him.

On examination he was in good health, quiet and apathetic, waiting until spoken to and answering with few words. His Binet I.Q. was 95. He did Raven's progressive matrices with some show of interest and scored 42 (Grade III). After several interviews a good rapport was obtained but he disclosed little useful information. He improved greatly during his time in the remand home: made good contacts with other boys, attended in the class room, read books with evident pleasure and could relate the story afterwards. He thus presented a picture of chronic apathy and depression, thought to be due to insufficient mothering as a baby, reinforced by long separation from home, loss of his father, and finally returning to an insecure home from which his mother was absent most of the day. It was felt that this chronically disturbed boy would be better away from home for a time, and that his outstanding need was the chance to make a firm emotional relationship with some understanding adult, in other terms, to gain a transference with someone who would know its significance and how

The remaining charges were evidently *not* considered indications for a special report and I would draw particular attention to the "breach of probation" and the "beyond control" cases.

Table II suggests in general that repetition of offence is not considered an indication for

forces, personality traits, "conflict" or neurotic delinquency, and the psychoses and organic conditions, has been adapted from a paper written by D. M. Levy (1932).

The psychiatrist (as opposed to the social worker) is mainly concerned with delinquency caused by personality traits and by "conflict" or neurotic mechanisms, and these factors, particularly in combination with other factors, are seen to be as well represented in the non-referred as in the referred group. As would be expected the cases showing combinations of factors appear to be the most difficult to recognize. The impression is gained (and particularly so in reading through the actual case-histories) that there was as great a need for psychiatric work in the one group as in the other. A similar impression has been gained in remand homes outside London.

The ages in the two groups have also been compared. In the non-referred group there is a peak age at 11 years while that of the referred group, as in most British studies in delinquency, is at 13 years. The percentage of children of 11 years and younger in the non-referred group was 28 while in the referred group it was 24 so that youthfulness is evidently not a usual indication for investigation.

It is clear to anyone who knows the difficulties which delinquent children offer, that it is impossible to recognize all the cases in need of special investigation and treatment unless all are examined fully as a routine. The following two cases are examples from the non-referred group.

CASE I.—A boy of 12 years, brought to court by his parents as beyond their control because he habitually stole from shops, truanted from school, stayed out late, was insolent and bad mannered.

The percentage of children of 11 years and younger in the non-referred group was 28 while in the referred group it was 24 so that youthfulness is evidently not a usual indication for investigation.

Mrs. Madeleine J. Robinson, J.P.: I will deal very briefly with three points as they affect the magistrates in the juvenile court: (1) Psychiatric examination and diagnosis. (2) Psychiatric treatment. (3) The need for follow-up and research.

(1) It always seems to me that the juvenile court acts as a sieve sorting out the more serious cases. Is our present mesh fine enough to ensure that cases needing psychiatric examination will be spotted at the earliest possible moment? Or should all cases found proved see a psychiatrist either (a) during remand in custody, or (b) during remand on bail. Many magistrates would welcome such a system but it is clearly useless to ask for routine psychiatric reports unless adequate trained staff is available.

Personal experience forces me to the conclusion that the facilities in the remand home for diagnosis have been very inadequate in comparison with those provided at a good clinic. This has been unfortunate as the more serious cases are generally remanded in custody. Sometimes the reports received have been little more than a rehash of the probation officer's report and until recently, in London, parents were not even seen. During the war and the post-war period cases were frequently remanded in custody because the waiting lists at voluntary clinics and hospitals were so long that it was virtually impossible to obtain reports quickly on bail. Such a situation is obviously undesirable as a fortnight's remand in custody is often unnecessary and may antagonize parents who would otherwise be co-operative. The services of a full psychiatric team with adequate time for their examinations are essential if the work is to be done properly at remand homes and it should surely be possible for such a team to deal with cases on bail and to carry out treatment where necessary.

(2) At present, when treatment is recommended while the child remains at home, the whole procedure has to be started *de novo* at a clinic or a hospital. The contact made between the child and the psychiatrist at the Remand Home is broken and there may be a long wait before new appointments can be made and treatment started.

Treatment may break down, either: (a) Because parents are too overburdened or too unco-operative to secure regular attendance or to carry out advice, or (b) because the gravity of the offences committed or the home conditions make it impossible to leave the child at home. In the first case many probation officers feel that a closer co-operation between the psychiatrist and the probation officer, either direct or through the psychiatric social worker, might sometimes prevent a breakdown. Where this cannot be prevented and in cases in which it is clear at the outset that the child cannot remain at home, the courts find themselves in a difficult position if continued treatment is advised. With the best will in the world it is often impossible to secure treatment once the child is removed from home. It therefore seems clear that treatment must be developed for children in institutions of various kinds.

(3) At present magistrates have very limited opportunities of learning from experience, because often it is merely by chance that they see the result of their decisions after a period of time and they have little or no basis of fact behind their theories. The London Juvenile Court Chairmen have pressed the Home Secretary to take powers in the new Criminal Justice Bill to initiate or aid research, including investigation into the results of treatment of various kinds. Such powers already exist in the new Health and Education Acts.

Mr. J. A. Rose, speaking as a magistrate who had experienced and appreciated the aid psychiatrists could and did render to the courts, said that not all magistrates were of the same mind. Many were sceptical and even regarded psychiatry as a fad. They had to be convinced of its value by argument, persuasion and, above all, by example. In the Provinces, where remand homes were often a long way away from the courts, liaison between the psychiatrist and the court had to be maintained by the probation officers. Though they were trained to value the aid of psychiatrists, they were rendered cynical, and therefore less co-operative, by recommendations which were completely impracticable.

The profession could greatly help to combat both the scepticism of magistrates and the cynicism of probation officers by taking trouble to ensure that their recommendations in particular cases were possible of application in the circumstances of the case, and were within the legal powers by which the action of the magistrates was limited. He quoted one example out of many which could be given, a case in which a psychiatrist recommended that a boy should be sent to a special school at a fee of ten guineas a week, when the total income of the family was round about six pounds a week.

He desired to see co-operation between magistrates and psychiatrists greatly extended and pleaded for assistance along the lines he had indicated.

to deal with it. Without this, the good qualities of an approved school would possibly be insufficient to ensure a permanent adaptation.

Where the psychiatrist has insufficient time to study his cases and to interview the parents, the magistrate will be justified in considering that as good a guess may be made in the court-room as elsewhere; also he may feel with a stubborn recurrent case, that the only disposal is an approved school and that once there it will not be of any advantage to the boy to have seen a psychiatrist. But the remand home psychiatrist should be able to help others than the magistrate—the parents to whom the child may return, the Home Office official whose task is to select a suitable school, the schoolmaster to whom he may be sent, the children's welfare officer who may have to select just the right foster-parent, and last but not least, he may be able directly to help the child itself. It is one of his tasks also to protect an approved school or other small community from the occasional case which is very disturbed, unreformable and likely to interfere with the welfare of the group as a whole. Such cases should be dealt with as maladjusted or epileptic or psychotic as the case may be. In the future the psychiatrist may be of use in selecting cases for, and in helping to run, therapeutic groups for delinquents or for parents of delinquents.

He should have sufficient knowledge of and interest in his cases to observe progress in the home or institution to which they will go and, if required, be prepared to give further advice and treatment. It is wrong that the remand home psychiatrist should not know the implications and results of his recommendations for only by follow-up studies is he likely to learn.

It behoves anyone who recommends an increased referring of children for psychiatric examinations, to consider any possible harmful effects entailed.

It will need additional staff. It will be costly, but prevention is likely to be cheaper than later maintenance of delinquent adults. For young and first offenders, and particularly if the remand is in custody, it will be at best a psychologically traumatic event which may increase feelings of resentment and thus foster anti-social tendencies. There is a certain stigma in the proceedings which may increase anxiety and feelings of inferiority in pre-disposed children. There is a risk of a child making bad associates, or being educated in delinquency and of a possible acceptance of his criminal destiny. One must consider also the feelings of the family and what will be the effects on the children in his street and school of his lurid story of "a cushy fortnight inside".

These are mostly problems of the remand home or centre and are arguments in favour of avoiding remand in custody rather than avoiding the actual examination. The latter also, however, may have its dangers.

The psychiatrist must guard against a sentimental attitude which may help the delinquent to rationalize his trouble as purely the fault of his parents or circumstances. Even where there is a demonstrable psychopathology in need of treatment, the salutary effect of appearing before the magistrate should not be depreciated by subsequent experience with the doctor.

It is possible also that a psychiatrist after a time may find problems where they are not, mistaking molehills for mountains. This will best be prevented by working also with non-delinquents, following up cases, and bearing in mind the normal surroundings and behaviour of the types of children with which he deals.

In conclusion, it seems desirable to examine the majority of cases and to avoid remand in custody whenever possible. Until this can be brought about the present methods of selection, as practised in the London Juvenile Courts, seem sound and effective though a proportion of cases needing special investigation and treatment escapes the mesh. When increased facilities will be available a start should be made by adding all youthful cases, all cases remanded in custody, and all cases charged with being "beyond control" or with breach of probation.

The remand home psychiatrist should be prepared and given the opportunity to extend his field of operation and thus justify the referring of cases to him for wider purposes than diagnosis and immediate disposal.

DISCUSSION ON THE DIETETIC SERVICE OF THE HOSPITALS OF THE FUTURE

Lord Woolton, in opening the discussion, said that when he was Minister of Food he found that some people thought of food merely as a means of satisfying the pangs of hunger, while others more fortunately situated ate for pleasure. It was true, however, that few people chose meals for their actual food value. Neither were they guided by the natural instinct for selecting the right foods, as nowadays they had to take whatever was available in the largest quantities; this applied especially to manual outdoor workers.

In hospitals he had been appalled by the way the nurses' food was cooked and prepared; a start might be made by improving this side of hospital catering. There would be a tremendous influence on the health of the nation if every convalescent could be given elementary lessons in food values. Advice on food values should be obtainable in all medical institutions and at Infant Welfare Clinics; at the latter particular attention should be given to the feeding of expectant and nursing mothers.

Sir Jack Drummond: In considering what should be the future developments of this vitally important part of hospital services it is useful to have as a background impressions gained from a study of the past and of the present.

It is not surprising, when one bears in mind the evolution of our hospitals from the charitable institutions for the very poor, which they were until well into the nineteenth century, that many ideas, deeply rooted in tradition, survived so long.

The provision of food for patients in earlier times was very much a secondary consideration. One square meal a day, whether the diet was full or low, was thought to be adequate whilst parsimony in the kitchen was regarded as commendable. It is in this early history that we can clearly trace the origin of the one cooked meal a day, still a feature of not a few hospitals, of divided control, of the confused interrelation between nursing and catering and of the misdirected efforts towards cutting the cost of food so often made by hospital managements.

In 1942 I was privileged to be invited to become Chairman of a special Committee set up by King Edward's Hospital Fund to examine and report upon hospital diets.

Dr. J. D. W. Pearce: It is important to bear in mind, when assessing the adequacy of psychiatric reports, the facilities which the psychiatrist has for the investigation of his patients. There have been instances where the time available and the information furnished to the psychiatrist by other sources have been so meagre as seriously to cripple him in his work. Reports for courts should be short and very much to the point. Opinions should be expressed quite clearly and in simple language. It is irritating for a magistrate to find that the psychiatric report includes long excerpts from the probation officer's report. Professor Kennedy referred to the need to regard mental defect not simply as intellectual defect, but also as including temperament defect. My own experience has been that the largest single group of juvenile delinquents is that in which temperamental instability is the most prominent feature. Where this is really severe and amounts to psychopathic personality proper, the ordinary approved school does not seem to be the proper milieu for the case, and there is quite urgent need to make special provision for such cases, both male and female; special approved schools or colonies may be the solution.

In the Criminal Justice Bill of 1947 the provision of State Remand Homes has been omitted. In the 1938 version of the Criminal Justice Bill provision was made for such Homes, which would in point of fact be the observation centres, to the need for which Professor Kennedy has referred. Such State Remand Homes were also to have dealt with difficult cases in approved schools, such cases being sent to the State Remand Home for a period not exceeding three months. It is to be hoped that they will be reinstated in the new Bill.

The Institute for Scientific Treatment of Delinquency has, on behalf of the Home Office, been giving trainee probation officers comprehensive, good, general training in psychiatry. I myself have advised such trainees to contact their local psychiatric services in their own districts, and as these officers have some insight into psychiatric work, they are no doubt quite capable of assessing how good or how bad such local services are. Similarly elsewhere I have advised general practitioners faced with problems of delinquency to co-operate with the probation officer and to seek his help and advice where necessary.

Finally, surely the time has come to amend those laws which conflict so patently with the known laws of biology. Examples of these are the age limits at which a boy can have carnal knowledge, or a child have *mens rea*. In some cases the whole situation becomes absurd, e.g. where a boy under the age of 14, who on all the facts has committed a rape, cannot be charged with this as the law holds that until he reaches his fourteenth birthday he cannot have carnal knowledge.

DISCUSSION ON THE DIETETIC SERVICE OF THE HOSPITALS OF THE FUTURE

Lord Woolton, in opening the discussion, said that when he was Minister of Food he found that some people thought of food merely as a means of satisfying the pangs of hunger, while others more fortunately situated ate for pleasure. It was true, however, that few people chose meals for their actual food value. Neither were they guided by the natural instinct for selecting the right foods, as nowadays they had to take whatever was available in the largest quantities; this applied especially to manual outdoor workers.

In hospitals he had been appalled by the way the nurses' food was cooked and prepared; a start might be made by improving this side of hospital catering. There would be a tremendous influence on the health of the nation if every convalescent could be given elementary lessons in food values. Advice on food values should be obtainable in all medical institutions and at Infant Welfare Clinics; at the latter particular attention should be given to the feeding of expectant and nursing mothers.

Sir Jack Drummond: In considering what should be the future developments of this vitally important part of hospital services it is useful to have as a background impressions gained from a study of the past and of the present.

It is not surprising, when one bears in mind the evolution of our hospitals from the charitable institutions for the very poor, which they were until well into the nineteenth century, that many ideas, deeply rooted in tradition, survived so long.

The provision of food for patients in earlier times was very much a secondary consideration. One square meal a day, whether the diet was full or low, was thought to be adequate whilst parsimony in the kitchen was regarded as commendable. It is in this early history that we can clearly trace the origin of the one cooked meal a day, still a feature of not a few hospitals, of divided control, of the confused interrelation between nursing and catering and of the misdirected efforts towards cutting the cost of food so often made by hospital managements.

In 1942 I was privileged to be invited to become Chairman of a special Committee set up by King Edward's Hospital Fund to examine and report upon hospital diets.

Dr. J. D. W. Pearce: It is important to bear in mind, when assessing the adequacy of psychiatric reports, the facilities which the psychiatrist has for the investigation of his patients. There have been instances where the time available and the information furnished to the psychiatrist by other sources have been so meagre as seriously to cripple him in his work. Reports for courts should be short and very much to the point. Opinions should be expressed quite clearly and in simple language. It is irritating for a magistrate to find that the psychiatric report includes long excerpts from the probation officer's report. Professor Kennedy referred to the need to regard mental defect not simply as intellectual defect, but also as including temperament defect. My own experience has been that the largest single group of juvenile delinquents is that in which temperamental instability is the most prominent feature. Where this is really severe and amounts to psychopathic personality proper, the ordinary approved school does not seem to be the proper milieu for the case, and there is quite urgent need to make special provision for such cases, both male and female; special approved schools or colonies may be the solution.

In the Criminal Justice Bill of 1947 the provision of State Remand Homes has been omitted. In the 1938 version of the Criminal Justice Bill provision was made for such Homes, which would in point of fact be the observation centres, to the need for which Professor Kennedy has referred. Such State Remand Homes were also to have dealt with difficult cases in approved schools, such cases being sent to the State Remand Home for a period not exceeding three months. It is to be hoped that they will be reinstated in the new Bill.

The Institute for Scientific Treatment of Delinquency has, on behalf of the Home Office, been giving trainee probation officers comprehensive, good, general training in psychiatry. I myself have advised such trainees to contact their local psychiatric services in their own districts, and as these officers have some insight into psychiatric work, they are no doubt quite capable of assessing how good or how bad such local services are. Similarly elsewhere I have advised general practitioners faced with problems of delinquency to co-operate with the probation officer and to seek his help and advice where necessary.

Finally, surely the time has come to amend those laws which conflict so patently with the known laws of biology. Examples of these are the age limits at which a boy can have carnal knowledge, or a child have *mens rea*. In some cases the whole situation becomes absurd, e.g. where a boy under the age of 14, who on all the facts has committed a rape, cannot be charged with this as the law holds that until he reaches his fourteenth birthday he cannot have carnal knowledge.

with the feeding of the patient. Miss Broatch has recently visited the U.S.A. to study their systems of hospital feeding. In many respects they are far ahead of us. Catering is almost everywhere unified and separated from nursing. Dietitians dominate the picture there, but those concerned with hospital administration are now admitting that they have gone a bit too far in handing over control to these experts. The personal touch between nurse and patient has suffered.

The members of the King's Fund Diet Committee feel that this important contact should be maintained. Every stage in the provision of food for the patients should be under the Catering Department until the meals reach the ward. Then, the nursing staff, who know the likes, dislikes and whims of the patient, should take over the actual service.

Dr. H. L. Marriott: Food in hospitals is a subject of immense importance in regard to the physical and psychological welfare of the patients. Their physical nutrition is a matter of significance in all but the most trivial medical and surgical conditions while in perhaps 30% of the total patients of an average general hospital suitable special dieting is the chief factor in treatment. One has only to think of such common conditions as diabetes, peptic ulcer, liver affections, sprue, prolonged fevers, conditions of protein depletion and conditions of fluid balance variations.

The psychological aspect of the feeding of hospital patients should need no emphasis. Anyone who has had an illness well knows that meals are most important events in his day-to-day life as a patient.

Unquestionably "the food service should be regarded as one of the essential remedial services offered by the hospitals" (King's Fund Report, 1943).

The aims of the food service should be to provide abundant food of first-class quality, well cooked and attractively served, with plenty of variety and choice. Furthermore, the food supplied to each patient should be nutritionally adequate and appropriate for his needs whether he belongs to the majority of patients who merely need good feeding or to the large minority needing special diets.

Our present hospital food services for patients and nurses do not fulfil these aims though, fortunately, the tendency is one of improvement. The lamentable facts of the matter were admirably demonstrated in the classic Memorandum on Hospital Diet published by King Edward's Fund in 1943.

The main cause of the low standard of past and present hospital feeding lies in the fact that hitherto the medical and nursing professions have failed to attach sufficient real importance to feeding, and many individual doctors and nurses have lacked accurate knowledge of nutritional facts. Our ignorance has been partly due to the relative newness of the science of nutrition but also largely to the fact that food is so familiar that we are apt to assume that we know all about it and have little to learn, whereas we treat with much more respect and humility subjects seemingly more recondite such, for example, as the rhesus factor or radiotherapy.

Perhaps the most basic elements of nutritional knowledge concern the simple facts of the daily dietary requirements of man (water, calories, protein, mineral salts and vitamins) and the knowledge needed to translate these requirements into terms of food—the food values of the common foods such as milk, meat, fish, eggs, bread, butter and sugar. Experience in consultations and in examining medical students and nurses suggests that these simple facts are not well known. Yet these same doctors, nurses and students are simply bursting with knowledge about details relating to matters infinitely less practically important and far harder to grasp.

The first memorandum¹ issued by this Committee presented many grave criticisms of current practice. Cases were described in which the nutritive quality of the diets was seriously defective: daily intakes of protein as low as 40 grammes; of vitamin C, 3 to 6 mg.; of vitamin A, none at all for six consecutive days and calorie intakes as low as or lower than the bare basal requirement. The standard of cooking and of the service of meals was reported as, in general, deplorably low, whilst inefficiency of administration and waste often went hand in hand with divided responsibility and control.

A strong case was made out for bringing all branches of hospital catering under the control of a single Catering Department, with a competent catering expert assisted by a dietitian in charge.

After the publication of this memorandum the Senior Dietitian of the King's Fund, Miss Broatch, visited a large number of hospitals and advised the Governing Bodies. This experience provided the material for a second memorandum, issued in 1945, which was essentially constructive in character². It provided suggestions for the unification of hospital catering under a single and expert control, for establishing Diet and Catering Committees in each hospital, for improving financial control, for staffing kitchens and also gave helpful ideas about planning menus and the service of meals.

It is encouraging to know that many hospitals followed this lead and that much progress towards more efficient catering has been recorded. On the other hand, reports by the Fund's dietitians still often make depressing reading; monotony of diet; the same menu repeated on the same day of each week; unattractive service; cold food; sodden and discoloured vegetables; only one cooked meal a day; no alternative to milk puddings, so the dreary records read. These are bad enough, but the shock is even greater when one discovers, by no means infrequently, that no related records are kept of the purchase and issue of food or that the full rations and allowances are not taken up.

It must be recognized that catering is to-day a very highly skilled job. Purchasing in the best markets, contracts, checks on purchases, stocks and issues, expert supervision of a kitchen, and control of waste are not matters that a matron or a house-keeping sister can fairly be expected to deal with nowadays in addition to her main duties. The catering of a hospital should be run as efficiently and as smoothly as that of a good hotel.

The science of nutrition has expanded so rapidly in the past twenty or thirty years that it needs the knowledge of a well-qualified dietitian properly to plan diets, not only in regard to their nutritive value but also their variety and appeal. Here, again, the field has grown too wide for those whose primary training is in nursing to have more than a superficial knowledge.

The planning of, and choice of equipment for, hospital kitchens call for much to be done in the future. Restrictions on building and on supplies of apparatus make improvements difficult to achieve at the present time, but there should be serious thought given to plans for the future. It is often said that the kitchens of many of the smaller hotels and restaurants would not bear inspection. I can assure you that that is certainly true of some hospital kitchens, and they have not even the saving merit of producing eatable meals.

In one connexion it appears desirable to retain the contact of the nursing staff

¹Memorandum on Hospital Diet. King Edward's Hospital Fund, London, July 1943.

²Second Memorandum on Hospital Diet. King Edward's Hospital Fund, London, May 1945.

with the feeding of the patient. Miss Broatch has recently visited the U.S.A. to study their systems of hospital feeding. In many respects they are far ahead of us. Catering is almost everywhere unified and separated from nursing. Dietitians dominate the picture there, but those concerned with hospital administration are now admitting that they have gone a bit too far in handing over control to these experts. The personal touch between nurse and patient has suffered.

The members of the King's Fund Diet Committee feel that this important contact should be maintained. Every stage in the provision of food for the patients should be under the Catering Department until the meals reach the ward. Then, the nursing staff, who know the likes, dislikes and whims of the patient, should take over the actual service.

Dr. H. L. Marriott: Food in hospitals is a subject of immense importance in regard to the physical and psychological welfare of the patients. Their physical nutrition is a matter of significance in all but the most trivial medical and surgical conditions while in perhaps 30% of the total patients of an average general hospital suitable special dieting is the chief factor in treatment. One has only to think of such common conditions as diabetes, peptic ulcer, liver affections, sprue, prolonged fevers, conditions of protein depletion and conditions of fluid balance variations.

The psychological aspect of the feeding of hospital patients should need no emphasis. Anyone who has had an illness well knows that meals are most important events in his day-to-day life as a patient.

Unquestionably "the food service should be regarded as one of the essential remedial services offered by the hospitals" (King's Fund Report, 1943).

The aims of the food service should be to provide abundant food of first-class quality, well cooked and attractively served, with plenty of variety and choice. Furthermore, the food supplied to each patient should be nutritionally adequate and appropriate for his needs whether he belongs to the majority of patients who merely need good feeding or to the large minority needing special diets.

Our present hospital food services for patients and nurses do not fulfil these aims though, fortunately, the tendency is one of improvement. The lamentable facts of the matter were admirably demonstrated in the classic Memorandum on Hospital Diet published by King Edward's Fund in 1943.

The main cause of the low standard of past and present hospital feeding lies in the fact that hitherto the medical and nursing professions have failed to attach sufficient real importance to feeding, and many individual doctors and nurses have lacked accurate knowledge of nutritional facts. Our ignorance has been partly due to the relative newness of the science of nutrition but also largely to the fact that food is so familiar that we are apt to assume that we know all about it and have little to learn, whereas we treat with much more respect and humility subjects seemingly more recondite such, for example, as the rhesus factor or radiotherapy.

Perhaps the most basic elements of nutritional knowledge concern the simple facts of the daily dietary requirements of man (water, calories, protein, mineral salts and vitamins) and the knowledge needed to translate these requirements into terms of food—the food values of the common foods such as milk, meat, fish, eggs, bread, butter and sugar. Experience in consultations and in examining medical students and nurses suggests that these simple facts are not well known. Yet these same doctors, nurses and students are simply bursting with knowledge about details relating to matters infinitely less practically important and far harder to grasp.

The first preliminary to getting our patients properly fed is that everyone in or connected with our professions must become imbued with the importance of feeding and primed with accurate nutritional knowledge. The onus for achieving this general attitude of mind lies particularly on those of us who are teachers of Medicine. Especially must we try also to convince our administrative boards of Governors and administrative officials that first-class food for the patients must be one of their chief aims, more important even than wonderful operating theatres, superb X-ray departments or magnificent board-rooms.

A corollary of the recognition of the necessity for better food services is that hospital managements must spend much more money on food and the food services. In the past hospital food has unfortunately been mainly scrutinized by hospital managers from the point of view of economy of expenditure. This emphatically must stop and their first preoccupation must become the quality of the remedial food services.

There should be a hospital Food Committee which should rank as one of the most important committees of the hospital with a forceful Chairman. The committee should meet not less than once a month and it should contain members of the hospital board, members of the medical staff, the superintendent, the caterer, the dietitian and the matron. The Food Committee should appoint from its members food inspectors who pay surprise visits, at least weekly, to wards, kitchens, &c., and who should concern themselves primarily with the quality of the food services and secondarily with matters of economy.

At the Middlesex Hospital we have had such a Food Committee for over two years and it has been very successful. Its success has largely been due to the voluntary work of its Chairman, Mr. W. B. Morison—a member of the lay board.

A catering officer should be responsible for all matters affecting food, including its buying, preparation and service, thus ensuring that a single individual is responsible for the hospital food. The catering officer should be the one person ultimately responsible, and should be regarded as subordinate only to the superintendent. The catering officer must be supported by provision for the food service of adequate personnel, accommodation and equipment—especially personnel; the service of food to the individual patient would seem best left a responsibility of the nursing staff, who have special knowledge of each patient.

Special diets should be the responsibility of the dietitian or of a special dietitian if the catering officer is a dietitian, and should be provided from a special diet kitchen or subdivision of the main kitchen. This special dietitian has in her hands the main form of treatment for perhaps one-third of the patients. If the catering officer is not a dietitian, then she will be the adviser on the more specialized aspects of hospital dietetics.

The dietitian must have adequate staff and facilities not only for routine day-to-day treatment but also to co-operate in research work requiring the provision of special diets. I would like to pay tribute to the great pioneer work done by the lady dietitians of this country and to draw the attention of the meeting to the great shortage of trained dietitians.

Captain H. Brierley: I am a hospital administrator who has spent many years managing the diet department. Hospital catering should be carried out by an expert caterer with some knowledge of dietetics who would be responsible for the whole diet department from the buying to the service of the food. In certain cases it

may be advisable for a hospital to appoint a dietitian to the post, but unfortunately few dietitians have sufficient good catering experience. I maintain, however, that good catering is the first essential and that a correct diet will follow. In large hospitals I think it is wise for the caterer to have a trained dietitian on his or her staff, and if this is a nurse dietitian, so much the better; she then acts as a very good liaison officer between the nursing staff and the caterer who should be directly responsible to the senior administrative officer. Any hospital feeding 200 patients plus staff should have a caterer and a dietitian and I am sure the money spent on salaries will not be wasted. The caterer must be allowed to have sufficient, well-paid, skilled staff to assist him and an up-to-date department with modern equipment. The department must have adequate offices so that there can be complete control of the ordering, checking, costing and stocktaking. There must be good central stores for all types of food where they may be properly stored and then prepared centrally by trained staff, as, for example, a butcher's shop where carcasses can be cut up and prepared, a fish shop where fish can be filleted, a butter room, a milk room, &c. There should also be a vegetable preparation room where all vegetables can be prepared for the kitchens centrally under supervision. The dry goods stores should be adequate and be provided with vermin-proof bins.

The dietetic service is divided into six main parts, the buying, storing, checking and costing, menu making, cooking and service. The menus should be the responsibility of the caterer, but they must be prepared in consultation with the dietitian and the chefs and they should be scrutinized and criticized from time to time by the senior executive officer. It is so very easy to get slack in drafting menus and in the past hospitals have been justifiably criticized for disgraceful planning of the food.

There should be adequate choice on the menus so that almost every diet can be catered for by the person who is ordering from the ward.

Cooking.—The number and general layout of kitchens is a most disputed subject. Some people advocate one large kitchen as being more economical and others believe that each ward or floor should have its own kitchen. I personally think that there is a happy medium, but certainly in a large hospital there should be more than one. I myself like one kitchen for patients, one for all staff and one for private wards. In addition it is wise to have a central pastry and sweet kitchen, under a skilled chef, which can serve everyone, as there is more satisfaction given and more economy carried out by a first-class pastry kitchen than in any other type of kitchen at the present time. I also advocate a central salad preparation room for everyone so that all salads and hors d'œuvres can be prepared under cool conditions and properly supervised away from the cooking.

I think a dietetic kitchen is desirable but this should be run as an annexe off one of the main kitchens so that reasonable economy can be exercised. It is absurd for a dietitian to be boiling a small saucepan of potatoes whilst exactly the same potatoes are being cooked next door. The dietitian should use the general facilities as far as possible. This special kitchen should be used for all highly specialized diets that need *separate* cooking, for all research diets and for training student dietitians. It should not be abused and one must therefore have a sensible dietitian in charge—not a crank.

So much for kitchens and cooking. The next essential is first-class delivery and this depends on the geography of the hospital. The food must be really hot when it leaves the kitchen and it must be conveyed in properly constructed and covered dishes in either electrically heated or insulated trolleys. The food must be delivered punctually and in the least possible time. This necessitates good administration.

The service of the food is a most important side. I think it should be under the supervision of the Sister and not the dietitian. The nurse knows much more about the patient and can see so much better to the helpless patient. It is so useless for a smart-looking dietetic student to take to a patient a beautiful tray and place it so that the patient cannot reach it, or possibly the patient may not be able to feed himself, and this is where the trained nurse should supervise. I think the dietitian should visit the wards regularly both at mealtimes and other times and advise on diets, also, should the hospital be training dietetic students, these students should spend part of each day working under the direction of the ward Sister.

The actual service can be done direct from the electric trolley going from bed to bed or the food can be served from a properly fitted ward servery. I myself think the latter is best and can be done more satisfactorily.

Every patient for every meal should have a tray, properly laid with good cutlery, salt and pepper pots and freshly filled clean glasses, taken in by a nurse or student dietitian one at a time. The plates should each have a cover which is removed by the nurse when she places the tray.

Hospitals should provide four attractive well-served meals in each day with plenty of variety for the patients and only one of them, namely tea, should be prepared in the wards.

Miss M. C. Broatch: *It is not sufficient for hospitals to appoint a catering officer and expect the feeding to improve immediately. The officer appointed must have the full backing of the Committee of Management; without this he will fail. The hospitals where this has happened must realize that it is those in authority who probably failed in their responsibility and not the Catering Officer. Sir Jack Drummond has referred to the service of meals to patients in America, where it has been entirely divorced from nursing. In the second Memorandum on Hospital Diet, it was recommended that the service of food was an important part of the nurses' duties. Nevertheless, this service is in danger of breaking down, unless steps are taken to see that due importance is given to the teaching of nutrition to nurses, not only in theory but in its application in the daily routine care of the patient.*

Miss D. F. Hollingsworth, *Chairman of the British Dietetic Association, spoke of the training of dietitians and of the difficulties involved in adapting existing trainings so that they may produce well-qualified dietitians fitted to fill the many good posts at present advertised. In particular, she mentioned the problem of deciding, for example, how much chemistry, or, at the other end of the academic scale, how much institutional management the dietetic student should be taught. She stressed the need for the help, encouragement and support of the medical profession both in the training of dietetic students and for the trained dietitian who frequently encounters great difficulties in a profession which in this country is still in its infancy.*

Miss Rose M. Simmonds *said that hospital authorities put the cart before the horse when they trained dietitians to produce special diets for a few individual patients instead of putting the emphasis on efficient catering and good cooking for all patients and staff. Until 1939 diet in hospitals (largely supplemented by patients' friends) consisted of one main meal at midday, the other meals consisted mostly of bread and butter with tea or soup. Light meals for gastric cases were invariably steamed fish and milk pudding. But not all special diets to-day provided adequate amounts of the essential nutrients. Recent analysis of obesity and low-salt diets showed low values of calcium, iron and the B vitamins. This was important because such diets were usually continued for long periods.*

During and since the war it had been found that good nutritive diets could be constructed from the available rations if these were all taken up and if "points" were spent to the best advantage. The only difference between special and full diets should be in their methods of presentation, and by the exercise of a little ingenuity the same foods could be made to appear more varied.

Mr. W. B. Morison spoke on the value of a Food Committee in a hospital. He considered the knowledge that such a committee existed tended to keep all concerned on their toes; in addition it provided a means whereby suggestions and criticism could reach the Governing Body of a hospital through channels such as Staff meetings, Nurses Representative Council and Sisters Council. The secretary superintendent, the matron and the catering officer attended meetings of the committee which included lay and medical representatives. The assistant caterer, the head dietitian and the supervisor of the private-wing kitchens attended and submitted their reports so that all aspects of feeding in the hospital came under review monthly. The medical representatives were most useful and he himself, as Chairman of the Food Committee of the Middlesex Hospital, had received invaluable help from them. For instance he had asked them for a report on the tendency of special diets, and that report resulted in the Board and House Committee being informed that within a comparatively limited time there would be as many special diets as ordinary served to the wards, with all the complications these involved in respect of increased space, staff and equipment.

Dr. David G. Morgan said that in the old days, particularly in the pre-Listerian era, there was hardly a person in hospital who was not swinging a high temperature in the evening. Hospitals got into the habit of not providing cooked substantial suppers for these people as the average patient did not require it owing to his condition. Nowadays with penicillin therapy it was relatively uncommon for more than a few hospital patients to be pyrexial. Their appetites for cooked suppers were, therefore, good and this new demand must be met. He was glad to hear that the training of dietitians of the future must be better adapted for posts in hospital kitchens. In the past they were trained for and handled special diets only. They must, in the future, be capable of catering in its broadest sense and have the necessary knowledge both for the purchase of food and the management of kitchen personnel.

Professor John Yudkin said that the feeding of hospital patients could only be improved by the formation of food committees such as that at the Middlesex Hospital, which had been described. But the desire to form such committees depended largely on the interest of the clinicians, whose training in dietetics was often at present quite inadequate. It was mainly through a body such as the food committee that the clinician was made aware of the importance of food. And so the circle was complete. One could not expect to have a food committee unless the clinicians appreciated the importance of modern nutritional knowledge and yet the best way to teach the clinicians was through a food committee. The only way in which the vicious circle could be broken was by the employment of a far larger number of dietitians in hospitals. The fact that there was a dearth of hospital dietitians was chiefly due to the lack of recognition of their value and of their extensive training. This showed itself in the very low salaries at which many posts were advertised.

Dr. Philip Ellman said that an inferior surgical service would not be tolerated in any good hospital and a similar attitude should be adopted with regard to the dietetic service. It had been pointed out that good diet was as necessary to recovery of health as good nursing, surgery or medicine and, as the Joint Tuberculosis Council (Rep.

of Council on Wartime Diet, 1944) had recently reported, institutional food to-day was universally condemned for its monotony, bad cooking and not infrequently its inadequacy. Not only was a properly planned diet needed for purely physical health but eating was social function reacting on the patient's outlook and, as Sir Jack Drummond had pointed out, it was important that right through the buying, preparing, cooking and serving processes it should be organized scientifically. No hospital of the future could possibly be complete without a representative food advisory committee headed by a catering officer who should have adequate powers and facilities. Such minimum requirements were by no means impossible of fulfilment at the present time for during the war at an emergency hospital which had initially very primitive facilities, a food advisory committee of the hospital with a full representation of medical, nursing and administrative staff was able to overcome what appeared to be insuperable difficulties.

Hospital food in its raw state was generally of first quality. Its subsequent handling all too often reduced it to what was commonly known as "institutional food". With determination and goodwill this stigma should surely be overcome in the future. (See also Ellman P., *Post-Grad. med. J.* (1945) 21, 334.)

Dr. James Watt said that doctors in the main deserved the reproaches of Lord Woolton and Sir Jack Drummond over their ignorance of the dietary required by both patients and staff. There was, however, one type of hospital in which, for at least half a century, dietary as a factor in treatment had been fully appreciated, namely, in tuberculosis hospitals and sanatoria. In them, complaint of monotony, poor cooking or service was sometimes justified, but the adequacy of the diet was seldom questioned. Sir Jack Drummond seemed to infer that the appointment of a competent catering officer with wide authority was enough to ensure the proper dieting of patients and staff. A good catering officer, as had been said earlier, was not necessarily a good dietitian, neither was the dietitian necessarily a competent caterer. Neither of them could replace the physician in assessing the value of dietary in treatment. Dr. Marriott was right in asserting that to carry out his duties efficiently the catering officer must have guidance from a committee, which should include not only himself and the dietitian but also a physician, the matron and the chef and be presided over by a member of the committee of management.

DISCUSSION: PLASMA PROTEIN FRACTIONS

Dr. R. A. Kekwick (The Lister Institute): *Human Plasma Protein Fractionation.*

During the last ten years considerable advances have been made in our knowledge of the protein constitution of biological fluids and of tissues. These advances have been due chiefly to the application of the improved electrophoresis techniques introduced by Tiselius, in conjunction with the optical systems devised by Philpot, Svensson and Longsworth [see 1].

Although it is possible to isolate proteins by electrophoresis, the scale on which such separations can be carried out at present is very limited, and from this point of view the method can only be used on a research basis. In conjunction with the classical methods for the bulk fractionation of protein solutions, it has proved of inestimable advantage in affording a precise and independent means of controlling and improving the resolution of the methods.

In attempting to separate proteins in a relatively pure condition from a mixture in aqueous solution, there are several variables of which use can be made to establish conditions such that a desired protein can be caused to precipitate more or less completely, leaving others in solution.

The following variables determine the solubility in such a system: pH; salt concentration; temperature; total protein concentration; and when solvents are used, a fifth variable—the solvent concentration.

The separation of proteins has mostly been carried out in very concentrated salt solutions, in the region of 2–3 molar, the salting-out procedure. The disadvantages of this method are twofold. First, the products must be freed from the precipitating salt by dialysis, a procedure difficult to carry out under sterile conditions, a necessary restriction if the product is required for clinical purposes. Secondly, the interactions between proteins and salts appear to be more specific at low salt concentrations, the effects being masked at the concentrations required for salting-out.

If a solvent is used for reducing the solubility of a protein, the electrolyte content can be maintained in the low concentration range where effects are more specific. It is easier to add solvents to protein solutions, whilst maintaining aseptic precautions, than is the case with salt solutions. Finally, the majority of solvents which are suitable for this type of work tend to be bacteriostatic, are volatile and can be removed from the products by freeze drying *in vacuo*, an operation easily performed under sterile conditions. The following solvents have been used in the fractionation of proteins from aqueous solution, methanol, ethanol, acetone, dioxane and ether. All of these solvents tend to produce denaturation of dissolved proteins at room temperature, and other concomitant undesirable effects such as loss of biological activity. Consequently it is usually necessary to carry out such fractionations with careful control of temperature in a range from 0° to –10°C.

The protein constitution of human plasma.—In the electrophoretic examination of normal human plasma five components were originally distinguished: albumin, α , β and γ globulin, and fibrinogen. More recent studies indicate the existence of two α globulins, α_1 and α_2 , and two β globulins, β_1 and β_2 .

The quantitative electrophoretic analysis of normal human plasma shows it to be remarkably constant in constitution. The amounts of the various proteins expressed as a percentage of the total protein are about:

Albumin	α Globulin	β Globulin	γ Globulin	Fibrinogen
55.0	14	13.5	11	6.5

Although the plasma components revealed by electrophoresis display a reasonable degree of electrochemical homogeneity, it is important to appreciate that this does not imply absolute chemical or physiological homogeneity. The wide range of physiologically and immunologically active proteins detectable in plasma is apposite to this point, and also the fact that the electrophoretically homogeneous components are susceptible to further fractionation by solubility methods. Further, the activity of proteins associated with specific biological effects is frequently so high in relation to mass that the amounts present in plasma may be far below the power of resolution of the electrophoresis apparatus.

The further exploration of the possibilities of the fractionation of human plasma proteins with solvents were stimulated by the urgent needs of the war. Although plasma can be dried successfully from the frozen state, and will then under proper conditions retain its properties for an indefinite period, there are certain advantages in the provision of a stable liquid transfusion material.

The alcohol fractionation system [2].—The primary object of Cohn's work was the preparation of pure human serum albumin for transfusion. As the work progressed a secondary objective developed, to separate the plasma proteins other than albumin, into limited numbers of main fractions corresponding as closely as possible with the electrophoretic components. These main fractions then formed the basis of various subfractionations oriented with reference to specific biological activities.

TABLE I.—THE ETHANOL FRACTIONATION SYSTEM

Fraction	pH	% ethanol	Temp. °C.	Ionic concentration
I	7.4	8	—3	0.14
II + III ..	6.8	25	—5	0.09
IV	5.8	40	—5	0.09
V	4.8	40	—5	0.11

Details of the fractionation scheme developed by Cohn are given in Table I, which shows the conditions under which four main fractions are separated from plasma. The quantitative distribution of the proteins present in the fractions is given in Table II.

TABLE II.—DISTRIBUTION OF PROTEINS IN ALCOHOL FRACTIONATION

Fraction	Plasma	I	II + III	IV	V	VI
Albumin ..	33.2	0.2	0.7	1.0	29.0	0.3
α Globulin ..	8.4	0.2	1.8	5.4	0.6	0.3
β Globulin ..	7.8	0.8	6.2	3.1	—	—
γ Globulin ..	6.6	0.5	6.0	0.2	—	—
Fibrinogen ..	4.3	2.6	1.6	—	—	—

Figures are grammes protein from 1 litre of plasma.

Though fraction V is the only one which approaches electrophoretic homogeneity, the others tend to show the predominance of one component. Originally fractions II and III were separated individually, but it was found more convenient to separate them together and then to subfractionate. The subfractionation of II + III provides a second product approaching electrophoretic homogeneity, namely, γ globulin, and by further treatment of fraction I a substantially homogeneous fibrinogen may be obtained. The homogeneity of the albumin, fraction V, can be improved by crystallization.

The ether fractionation system [3, 4].—Ether can also be used as a precipitating agent in much the same manner as alcohol. Details of the system which is less extensive than that for alcohol are given in Table III.

TABLE III

Fraction	pH	% ether	Temp. °C.	Ionic concentration
Fibrinogen ..	7.2	11	0	0.14
Prothrombin ..	5.3	10	0	0.13
Globulin ..	5.3	17.5	-3.5	0.05

The residue after the removal of globulin consists of albumin and residual globulin. This can be frozen with excess ether to remove lipid and can be recovered in this way for use in transfusion. The globulin fraction is subfractionated to provide a fairly pure γ -globulin preparation.

THE CLINICAL APPLICATION OF PLASMA FRACTIONATION PRODUCTS

Perhaps the most versatile of the products of plasma fractionation are fibrinogen and thrombin [5]. Since the clotting time of fibrinogen-thrombin solutions can be accurately controlled, a liquid mixture can be applied locally, which subsequently clots. The tensile strength of fibrin clots, though also a function of other variables, increases with fibrinogen concentration, and solutions of fibrinogen up to ten times (2%) the corresponding concentration in plasma are readily attainable. The clots formed from such solutions have been used to suture severed nerves by a soldering type of process. Rather lower concentrations of fibrinogen provide, with thrombin, an excellent adhesive for the application and fixing of skin grafts, dispensing with the necessity for pressure dressings. Grafts fixed in this manner vascularize with extraordinary rapidity and the tendency to bronze pigmentation appears to be reduced.

Fibrinogen preparations also contain a material which is effective in reducing the whole blood clotting time in hæmophilia from, say, seventy-five minutes to around fifteen minutes. An injection of 10 ml. of a 2% solution will keep the clotting time at this level for about forty-eight hours [6, 7].

Fibrin films, resembling sheet cellophane in appearance, have been successfully used as dural substitute with marked absence of adhesion. The film is eventually replaced by fresh dural growth.

Somewhat less purified fibrinogen solutions are utilized in the production of fibrin foam. By suitable devices, these solutions are beaten to a finely dispersed foam which is set by adding thrombin and then dried from the frozen state. Such foams if rewetted tend to shrink rapidly, but this can be prevented by baking the dried foam at 130° to 170° C.

The dried foam will absorb almost its own volume of thrombin solution, and is used in conjunction with this for local hæmostasis in internal surgery. The foam is allowed to remain in situ following operative procedures, and eventually becomes organized into the tissue without scar formation.

It has been established that the antibodies in many infectious diseases are associated with the γ -globulin of normal adult plasma [8, 9, 10]. Concentrates of this protein containing 15 grammes protein/100 ml. have been very successfully utilized in the control of measles and may be useful in infectious hepatitis. For measles, intramuscular injections up to 5 ml. are required. The use of similar concentrates prepared from convalescent plasma pools from other infectious diseases, for example, mumps, has been examined.

The A and B isohæmo-agglutinins, which appear to be associated with β globulin, have been purified and concentrated from pools of plasma of suitable blood group. High titre sera are required for accurate blood group testing, and concentration methods make available the agglutinins from plasmas whose titre initially is too low.

Purified albumin solutions containing 25 grammes/100 ml. have been satisfactory for transfusion in cases of shock, and hypoproteinæmic œdema.

Further research may indicate the clinical usefulness of other fractions derived from human plasma.

Dr. Nicholas Martin: *The Electrophoretic Pattern of the Circulating Proteins.*

I. *Introduction.*—Electrophoresis may be defined as the phenomenon of the migration of "particles" in a medium, under the influence of a current passed through that medium. In so far as the phenomenon is related to the density of free charge on the surface of a given "particle", two "particles" or groups of "particles" in which the density of free surface charge differs will tend to separate when subjected simultaneously in the same medium to a current of controlled density.

While the study of this and allied phenomena has progressed vigorously for more than one hundred years [Lodge, 8, Picton, 18, Hardy, 6, Burton, 4], it was the technical advance introduced by Tiselius [21, 22, 23, 24] that enabled the principles to be applied with such success to the study of proteins. Prior to his work two major stumbling blocks existed, the disturbance of the boundaries of the migrating proteins by convection currents arising from the heat produced by the passage of a current sufficient to achieve separation in a reasonable time, and the lack of a convenient means of studying colourless moving boundaries. By the ingenious design of the cell, and by immersing it with the electrode vessels in a thermostatically controlled bath at low temperature, he was able to minimize disturbances from convection and to make sharply defined starting boundaries with relative ease. By adaptation of the Topley Schlieren principle he was able to devise a convenient means of visualizing colourless moving boundaries by following the change produced in refractive index of the medium by the presence of varying concentrations of protein.

II. *Some factors influencing quantitative analysis of the protein mosaic from Schlieren patterns.*—Diagram 1 shows in a highly simplified form the behaviour of a mixture of four proteins having differing mobilities, when, dissolved in a buffer solution, they are subject to the influence of a current of constant density. It demonstrates that in such a system only a limited quantity of the fastest and slowest component may be separated in a pure state, and that the more nearly the mobilities of the individual proteins approach each other, the more difficult it becomes to achieve this separation. Svensson [20], and MacLagan and Bunn [12] have both devised methods of "continuous return" by which more effective separation can be achieved in a single sample.

It is clear that in studying an ampholyte such as a protein, mobility will be affected by the pH of the surrounding medium. Indeed, one convenient test of electrophoretic homogeneity is that the protein isolated should move as one entity when examined over a varying range of hydrogen-ion concentration.

When making quantitative analysis of mixtures of proteins it is essential to take notice of the part played by the ionic constitution and concentration of the surrounding buffer and of the total concentration of protein subjected to electrophoretic analysis. Table I condensed from the literature illustrates the magnitude of variations to be expected from these effects. Further, since when using the Topley Schlieren principle it is refractive increment which is being measured, substances other than proteins, which may migrate with individual proteins, may contribute to the refractive increment attributed to that protein.

TABLE I

TABLE I

Protein conc. as mgs. N/ml.	Alb.	γ glöb.	Ionic conc.	Alb.	γ glob.
4.0	58.4%	9.8%	0.1	55%	7.8%
3.0	57.8%	9.8%	0.2	52%	11.7%

mobilities cm./volts/secs.					
pH 7.7					
Ionic strength of buffer 0.20%					
of neutral salt 0.18%					

Table I from data of Perlmann and Kaufmann [17].

III. *The protein mosaic in the normal subject.*—When normal adult human plasma is examined by the technique at a pH somewhat to the alkaline side of the physiological normal the protein mosaic is analysed into five main groups which are referred to as the albumins, the α globulins, the β globulins, fibrinogen and the γ globulins. The pattern does not differ markedly with sex or age with the exception that the fœtus and the newborn appear to have a relative excess of γ globulin, an excess not mirrored in the healthy pregnant woman. When serum is examined the fibrinogen “peak” is absent but frequently a small ill-defined residuum of material remains, travelling with a mobility intermediate between the β and γ globulins. If the pH of the buffer solution is raised to from 8.0 to 8.6 a globulin designated α_1 globulin may frequently be identified running between albumin and α_2 globulin. These electrophoretic patterns of human serum and plasma are not the patterns of pure protein but of the complexes of proteins with non-protein substances; the albumin fraction may contain carbohydrate and fatty acids—the α and β globulin fractions lipoids and steroids. Recently, a β lipoprotein has been described which contains 75% of lipid [16].

Analysis of the soluble proteins remaining after precipitation

* After Dole [5] †Perlmann [17] ‡Svensson [19].

Table II from data of Armstrong Budka *et al.* [2].

Table II shows a comparison of the separation of normal plasma proteins obtained by some of the common salting-out techniques used in routine laboratory procedures, with electrophoretic analysis. The electrophoretic analysis in each case refers to that portion of the protein mosaic remaining in solution. It demonstrates that these salting-out methods do not give a cleavage which corresponds to any exact point on the electrophoretic pattern when normal plasma is examined. In general the proportions of albumin to globulin electrophoretically are some 30% lower than those established by salting-out techniques in normal sera [5]. In sera abnormal with respect to their protein content where entrainment and other physico-chemical factors may complicate the picture, the deviation may be more marked. Thus in acute infective

Dr. Nicholas Martin: *The Electrophoretic Pattern of the Circulating Proteins.*

I. *Introduction.*—Electrophoresis may be defined as the phenomenon of the migration of "particles" in a medium, under the influence of a current passed through that medium. In so far as the phenomenon is related to the density of free charge on the surface of a given "particle", two "particles" or groups of "particles" in which the density of free surface charge differs will tend to separate when subjected simultaneously in the same medium to a current of controlled density.

While the study of this and allied phenomena has progressed vigorously for more than one hundred years [Lodge, 8, Picton, 18, Hardy, 6, Burton, 4], it was the technical advance introduced by Tiselius [21, 22, 23, 24] that enabled the principles to be applied with such success to the study of proteins. Prior to his work two major stumbling blocks existed, the disturbance of the boundaries of the migrating proteins by convection currents arising from the heat produced by the passage of a current sufficient to achieve separation in a reasonable time, and the lack of a convenient means of studying colourless moving boundaries. By the ingenious design of the cell, and by immersing it with the electrode vessels in a thermostatically controlled bath at low temperature, he was able to minimize disturbances from convection and to make sharply defined starting boundaries with relative ease. By adaptation of the Töpler Schlieren principle he was able to devise a convenient means of visualizing colourless moving boundaries by following the change produced in refractive index of the medium by the presence of varying concentrations of protein.

II. *Some factors influencing quantitative analysis of the protein mosaic from Schlieren patterns.*—Diagram 1 shows in a highly simplified form the behaviour of a mixture of four proteins having differing mobilities, when, dissolved in a buffer solution, they are subject to the influence of a current of constant density. It demonstrates that in such a system only a limited quantity of the fastest and slowest component may be separated in a pure state, and that the more nearly the mobilities of the individual proteins approach each other, the more difficult it becomes to achieve this separation. Svensson [20], and MacLagan and Bunn [12] have both devised methods of "continuous return" by which more effective separation can be achieved in a single sample.

It is clear that in studying an ampholyte such as a protein, mobility will be affected by the pH of the surrounding medium. Indeed, one convenient test of electrophoretic homogeneity is that the protein isolated should move as one entity when examined over a varying range of hydrogen-ion concentration.

When making quantitative analysis of mixtures of proteins it is essential to take notice of the part played by the ionic constitution and concentration of the surrounding buffer and of the total concentration of protein subjected to electrophoretic analysis. Table I condensed from the literature illustrates the magnitude of variations to be expected from these effects. Further, since when using the Töpler Schlieren principle it is refractive increment which is being measured, substances other than proteins, which may migrate with individual proteins, may contribute to the refractive increment attributed to that protein.

Fig. 1 illustrates electrophoretic analysis from two conditions involving an increase in mesenchymal tissue. 1A is from a proved case of Boeck's sarcoidosis and shows an increase in the slower-moving components of the protein mosaic.

1B and 1C are two analyses from cases of myelomatosis, the second on the day of death. Kekwick [7] demonstrated that cases of myelomatosis, indistinguishable clinically, fall into two groups by electrophoretic analysis, in the one group the great increase is in the area of mobility of the β globulins, in the other, in the area of the γ globulins. The cases shown fall into the second group having an enormous increase in globulin, moving with a mobility corresponding to γ globulins. The whole area is closely defined, implying that the proteins indicated by it are moving with a reasonably uniform velocity.

FIG. 1.—The direction of migration is from right to left.

DIAGRAM 1.—The arrow indicates the direction of migration, in this diagram to the +ve pole. The black area in the top diagram represents a solution of four proteins prior to switching on the current. The two "boundaries" between the protein solution and the buffer which separates it from the electrodes are marked A and D. The second diagram represents the state of affairs shortly after the current has been switched on. It will be seen that the most "advanced" boundary is now composed of the fastest moving component of the mixture only. The third diagram represents the position some time after the current has been running. The advanced boundary of the fastest component is well forward, but its "hind" boundary is still overlapped by the forward boundary of the next fastest moving component. It illustrates the limitations of the method in effecting separation of two components of closely related mobilities.

1D represents the isolation of the abnormal constituent from 1B by quantitative electrophoresis. The appearances would suggest that one was dealing with a homogeneous substance with regard to its electrophoretic properties, mobility studies placing it among the γ globulins. However, Professor Oncley very kindly submitted the material to ultracentrifugal analysis and demonstrated that it did in fact consist of three components with different sedimentation constants. At post-mortem proteins resembling the γ globulins were demonstrated in highest concentrations in those tissues most heavily infiltrated by tumour cells, being present in negligible amounts in other tissues. They were not identified in tissues from a normal submitted to parallel extraction [15].

Conclusion.—It cannot be too strongly stressed that electrophoresis is only one of many techniques which have proved of use in studying complex mixtures of macromolecules. Finally electrophoretic homogeneity should never be taken to imply either chemical or biological homogeneity. It does offer an extremely convenient way of analysing complex mixtures of proteins in solution with an accuracy—having regard

hepatitis the difference may be as much as 36% and in chronic liver damage 40% or more (Martin, unpublished data).

IV. *The protein mosaic in disease processes.*—In this brief survey it will only be possible to give a few illustrative examples of the alterations which may be demonstrated in the protein mosaic in disease. It must be stressed that in many conditions, as for instance extreme starvation, striking differences are not discernible by this technique, while in many other conditions the changes demonstrated are those which, with intelligent forethought, one might anticipate. Moreover the changes in pattern when they occur are in most instances not so much a characteristic of the individual disease process as of the host's reaction to that process. That reaction may be the same in conditions which, clinically, differ widely. In nephrosis, electrophoretic analysis demonstrates that the major contributors to the circulating plasma proteins are the α and β globulins [11]. It must be remembered as Longsworth and MacInnes [9] have pointed out that the lipoids, and more especially the cholesterol and allied steroids travelling in loose association with the β globulins contribute largely to the refractive increment demonstrable in that area of the pattern. Both in nephrosis and in obstructive jaundice the plasma cholesterol may be raised and in both these conditions one frequently detects an increase in material migrating with the velocity of the β globulins.

Examination of the urine in nephrosis shows that the protein passed in it is predominantly albumin with some β and some γ globulin [11].

Luetscher [10] studying a carbohydrate-free crystalline human albumin observed that at pH 4.0 it resolved into two components, the faster component contributing about 60% of the total. When the albumin from a nephrotic patient was examined the same resolution was observed but the ratio of the faster to the slower component was reversed. Bourdillon [3] had calculated that the molecular weight of human nephrotic albumin differed from that of normal human albumin.

In diseases involving the liver parenchyma the pattern varies with the stage and extent of the disease. In simple uncomplicated infective hepatitis—in the early stages there is a relative depression of the albumin with increase in the γ globulin. As the patient recovers the albumin tends to revert to a normal level and the circulating γ globulin level to drop. The α and β globulins may show some change, notably between the fourteenth and thirtieth days and it has been observed that their deviation from normal is greatest in those patients having a tendency to relapse [13]. That the actual recovery of the circulating albumin may not be so rapid, as superficial examination of the electrophoretic data would lead one to suppose, is shown in Table III where the total circulating components have been calculated on two

TABLE III

Table III from data of Svensson [20].

analyses in a moderately sick patient, the first toward the end of the first week, the second early in the fourth week during the recovery phase. It will be seen that whereas the level of the γ globulin has fallen to normal limits, the total amount of circulating albumin is still 15% below normal in the fourth week. In established chronic liver damage analyses show an absolute diminution in circulating albumin with an increase in the γ globulin which may represent 30% of the total circulating protein.

The Serious Limitations and Erroneous Indications of Biopsy in the Diagnosis of Tumours of Bone

By JAMES F. BRAILSFORD, M.D., Ph.D., F.R.C.P., F.I.C.S.

Radiologist, The Royal Cripples and The Queen Elizabeth Hospitals, Birmingham

THE clinical signs and symptoms of tumours of bone are so variable in their manifestations that except in a small proportion of cases they are of little or no value in determining the nature of a bone tumour.

These tumours occur at all ages from birth to old age. They show a great difference in their rate of growth; some ending fatally within a few months, others showing a slow progression over years, and in some cases, after a few years, a retrogression. They occur in patients who exhibit vivacity and all the robustness of the healthy, to patients with the anxiety, wasting and cachexia of the dying. Pain accompanying their growth may be negligible, or so severe that only morphia can give relief. In some cases tenderness may be so exquisite that the patient screams at the approach of the examining hand, whilst in others firm palpation may be permitted without any discomfort.

These tumours are so variable in all their characters and manifestations that they defy any scheme of classification. We should be lucky indeed if we could readily separate the simple from the malignant. They are so rare in any one surgeon's practice, unless he is a recognized authority to whom many of his colleagues refer their cases, that little practical experience in diagnosing and treating these bone tumours can be obtained; yet the general practice is for the surgeon to treat his own cases.

Yet there would appear to be some divergence of opinion as to who should treat these lesions. A contribution to a discussion on the diagnosis of bone tumours by a learned orthopædic surgeon was prefaced by his message: "There is no need for the pathologist or the radiologist to lose one wink of sleep over the diagnosis of a bone tumour for that is the province of the surgeon." These sentiments have recently been re-echoed from America, where Philip D. Wilson [2], speaking in support of the claim that bone tumours are the responsibility of the orthopædic surgeon, is quoted as saying: "I know in several centres there are excellent general surgeons caring for these patients and doing excellent work; yet I know of one instance not long ago when a Brodie's abscess was explored under the diagnosis of neoplasm. It needed exploration, it was the proper thing to do; but it seems to me a knowledge of bone lesions or bone pathology is necessary and certainly will help in the diagnosis. I think these men who are treating tumours will invariably have brought to their clinics a great many cases of non-neoplastic conditions which represent bone anomalies of various types which require orthopædic care. *They will undertake the treatment, when they are not properly qualified for it.*" It is not surprising to see accounts (and hear of many more) of amputations and other mutilations for tumours judged to be malignant, yet proving to be simple. But this does not apply solely to general surgeons or the Cottage Hospitals. Their work is based upon the teaching and practices of our University Hospitals and it is the work done in the latter which we must scrutinize if we are to assess the relative merits of the methods employed.

It is generally agreed that notwithstanding the recognition of the clinical examination as of the first importance this does not permit of the diagnosis of any bone

to the amount of material used—hitherto unobtainable by any means of parallel simplicity.

Dr. F. O. MacCallum asked Dr. Kekwick if it was known what temperature human serum γ globulin could be exposed to without alteration of its structure and antibody content. If certain viruses as well as antibodies might be present, it was desirable to know how they could be inactivated.

Dr. C. H. Gray, in answer to a question, stated that experiments he had performed in collaboration with Dr. Kekwick suggest that the binding of bilirubin by different fractions of the plasma proteins bears no relationship to the nature of the direct van den Bergh reaction.

Dr. L. F. Hewitt: A matter that tends to be overlooked is the question of the physiological and immunological significance of the plasma proteins. Knowledge of the distribution and physico-chemical properties of the fractions is accumulating but these are only symptoms of the function of the cells which produce the proteins and further knowledge is required of the mechanism of synthesis and site of origin of the plasma proteins. It seems fairly certain that different proteins originate in widely separated organs and cells, but detailed knowledge is lacking of the origin of both normal and pathological plasma protein fractions.

Dr. A. C. Dornhorst: Can Dr. Martin tell us whether bilirubin always migrates with the same protein fraction irrespective of the type of jaundice present? If not, does its behaviour throw any light on the mechanism of the van den Bergh reaction?

Dr. Kekwick, in reply: So far as I am aware no data as yet exist in the literature which would furnish a categorical reply to Dr. MacCallum's question.

Dr. Martin, in reply: I think that our investigation of the γ globulin in the plasma of myelomatosis is the beginning of the filling in of the gap in our knowledge to which Dr. Hewitt refers.

In reply to Dr. Dornhorst it seems probable that bilirubin is capable of combining with more than one protein fraction [14]. The precise mechanism of the van den Bergh reaction still remains to be elucidated.

malignancy. An examination of the reports on the histology of bone tumours reveals the indecision which the appearances produce. For, whereas in the descriptions of normal tissues we see the use of definite terms such as fibrous, cartilaginous, or osseous tissues, in the descriptions of pathological tissue we see the indecisive terms mucoïd, fibroid, chondroid, osteoid, muco-fibroid, fibro-chondroid, chondrosteoid, &c., terms which permit of considerable latitude of expression by different observers.

No more important contribution on this is made than in the latest publication by Platt [1] who used as illustrations photographs (3A and 4A) and photomicrographs (3B and 4B) of two cases; both of them he describes as osteogenic sarcoma of the upper end of the fibula. Both 3B and 4B are described as showing "the predominant cell was oat shaped" yet the photomicrographs present quite different pictures. The photographic appearances are also different; 3A showed the tumour protruding from the fascia at multiple sites as in a malignant growth, but 4A shows a more regular spindle-shaped tumour. 3 was of a patient who "died eighteen months after amputation", 4 was of a "patient who is living 13 years after the amputation". No radiographs of these lesions are produced but the subsequent histories bear out the macroscopic appearances rather than the histology. Several papers describing erroneous histological interpretations of multiple cases have been published by the author [see 10, 11, 12, 14, 15, and 16].

It would appear that students who have been taught with the typical material do not realize how seldom tumour tissue presents characteristic features, and there was good reason for Ewing [4] to state: "Few surgeons realize the limitations in the histological diagnosis of bone tumours and the conditions which simulate or accompany them."

(2) *How Should Biopsy be Performed—By Cutting Needle or Punch, or By What H. Platt [1] Describes as "Real Biopsy, Real Exposure and Removal of Tissue"?*

H. W. Meyerding [5] of the Mayo Clinic has stated: "I do not believe in needle biopsy, but prefer that which includes incision, inspection of the tumour and removal of an adequate portion of tissue for pathological examination." Yet there are many other surgeons who prefer to use a cutting needle or punch to obtain tissue for histological examination.

(3) *Why was Punch or Needle Biopsy Introduced?*

It was held by many surgeons that incision into malignant tumours disseminated the malignant cells through the medium of the cut vessels. Diathermy cutting was hailed with enthusiasm because it was thought that this method of cutting would prevent dissemination of the cells by surgery. Following biopsy a good proportion of patients with sarcoma develop metastases; but then many patients, when first reporting because of a tumour, show metastases, and we cannot say that metastases are not present though radiographs fail to detect them—it requires time before these secondary lesions arrive at a size which permits of radiographic visualization, what I have called [17] "the latent negative radiographic period". But the radiographic appearances before and after biopsy certainly suggest dissemination. We may see changes within the affected bone but no irregularity of the surface before biopsy, but the appearances following biopsy suggest that the bone has exploded at the site, for the bone becomes fragmented and sun-ray spicules appear to shoot out in all directions.

We know that surgical exploration of the affected area in the acute phase of scurvy or myositis ossificans results in considerable extension of the ossific cells for this has been demonstrated radiographically on many occasions; see S. L. Baker's illustrations [6]. It results in further invalidism and more permanent and extensive damage. Surgical incisions, and particularly the removal of large pieces of tissue, tend to destroy the scaffolding on which repair will be laid down if the lesion proves to be

tumour in its early stages. As Bloodgood stated: "In former years when malignant disease could be recognized clinically there were no cures." Consequently, even the orthopaedic surgeon must look elsewhere for evidence. Because the histology of normal tissues is characteristic, and pathology is associated with very marked changes, to histology we turned for conclusive evidence. Though there is considerable ground for distrusting the interpretation of histological appearances, a widespread belief prevails in the infallibility of histological evidence. So firmly is this belief held that if the subsequent history of the case differs from the forecast given, it is the pathologist, however eminent, who is blamed for the erroneous interpretation, rather than the vagaries of the histology.

Certain leading authorities hold that biopsy affords the means for fully proving the nature of bone tumours and always resort to biopsy prior to any major surgical measures. Most radiotherapists act likewise. Thus recently Platt [1], reviewing 161 cases, claims 23 five-year survivals, and states: "Twenty-two of these patients treated by radical operation are *fully proven cases*, but in one, a pelvic sarcoma, *proof from biopsy* was not forthcoming." "Forty-one patients in this series of short survivals died within a year of operative treatment. At first sight this is a melancholy picture, but when we consider that in 128 accessible tumours treated by radical operative procedures, 79 patients have survived over two years and 23 of these five years and more, the current view, *that the general outlook on bone sarcomata as a whole is by no means tragic*, is reinforced." Have we any right to reinforce this outlook?

LIMITATIONS OF BIOPSY

If the infallibility of biopsy could be substantiated, the risks of anaesthesia, surgical exploration and all that it means in additional damage, dispersal of tumour cells, &c., and the mental and physical pain caused thereby—I can recollect two deaths which took place within a short time during biopsy on what proved to be simple lesions—could possibly be regarded as negligible or at any rate justifiable. Before we resort to biopsy we should satisfy ourselves with satisfactory answers to the following questions:

(1) *Can the Findings of Biopsy be Relied Upon?*

L. C. D. Hermitte and F. Ellis state [18]: "The diagnosis of the true nature of a tumour (particularly of a neoplasm) must finally rest upon histological evidence." Microscopical examination of animal tissues reveals that the normal tissues have a characteristic cellular structure which permits us to identify them. The histologist, Reichart, promulgated the concept that bone, cartilage, tendon, fibrous and elastic tissue, derived from the mesenchyme, are all adaptations of, or developments from, the primitive connective tissue. Subsequently Leriche and Policard [3] brought forward evidence in support of their suggestion that these mature tissues may be induced, under certain influences, to revert to their primitive state and then undergo ossification. Not only can the mature normal mesenchymatous tissues be recognized readily from their microscopical appearances, but abnormalities in their size, shape, disposition and staining features also. Certain bone tumours present striking histological features as they do radiographic features, which may be regarded as typical indications of malignancy, and it is the material from these which is used for teaching purposes because the abnormal features are so striking. Unfortunately for diagnosis some of the cellular features which are regarded as characteristic of the malignant lesion are found under certain circumstances in tissues of a simple nature, but, on the other hand, they may be absent from the tissue of the frankly malignant tumours. This was appreciated by Ewing [4] who stated: "In the average specimen of callus the proliferative activity of fibroblasts, osteoblasts and endothelium is quite remarkable and often presents a picture which is difficult to separate from sarcoma." Histological preparations of bone tumours have been submitted to multiple pathologists who have given reports on them which in any one case have varied from simplicity to high

spaces containing loose connective tissue. *There is little evidence of tumour growth and none of malignancy.*

"19.4.47: Patient readmitted to hospital as tumour mass has recurred. Radiograph revealed extension of growth. ? sarcoma.

"21.4.47: *Operation* (3rd).—Exposure of lower end of femur—large sarcoma found at lower end of femur. Portions sent for biopsy. Report of Pathologist: 'Sarcomatous changes in neoplasm at lower part of right femur. *Chondrosarcoma of femur.*'

"24.5.47: *Operation* (4th).—Disarticulation at right hip-joint. Patient made a good recovery and was sent home to await an artificial limb."

Note that *this patient had four anæsthetics and surgical explorations* and that the interpretation of simplicity of the histological material at the first biopsy and even after the second resection of the whole mass was erroneous, though there was already a radiographic interpretation of malignancy.

The second case was published by S. L. Baker [6] (his Case 1):—

A boy aged 4½ years: "15.7.41 slipped on the floor and sustained a spiral fracture of the mid-shaft of the right femur for which he was admitted to hospital. A mass developed in relation to the fracture site, within four weeks this had reached a considerable size and in an X-ray taken on 11.8.41 the central part around the fracture showed much calcification and a layer of new periosteal bone could be seen extending from this up the shaft. By this time the thigh was greatly enlarged, felt hot and showed many distended veins and the appearances so closely resembled a rapidly growing sarcoma that a biopsy was performed on 19.8.41, five weeks after fracture. *Disarticulation at the hip-joint was considered but regarded as too risky and of doubtful value and palliative treatment was decided on.* A note made at this time 2.9.41 remarks: 'Huge swelling of right thigh from below knee to above groin, œdematous, hot, distended veins on surface. *Tumour fungating through biopsy scar.*' X-ray treatment 3,000 r spread over three weeks was given between 4.9.41 and 26.9.41. The mass in the thigh gradually became harder and the biopsy incision healed. About this time I was shown a section which at first I considered showed a chondrosarcoma but later had expressed doubt upon. An X-ray taken 7.6.44, nearly three years after fracture, shows that the callus had been largely reconstructed and now formed part of an expanded but porosed and trabeculated femur shaft with no signs of the fracture site."

He comments on this as follows: "Chondrosarcoma was, I think, not an unjustifiable diagnosis. Had the leg been removed in my Case 1 *it would have been impossible to prove that it was not a sarcoma cured by amputation.*" But considerable doubt could have been thrown upon the diagnosis by reference to the author's previous paper [8] and, in view of the proved nature of the lesion, the record "Tumour fungating through the biopsy scar" would appear to be inaccurate. That it was a *real biopsy* is indicated by the recital of descriptions of the material, i.e. "The material consisted of several pieces of tissue, some measuring as much as 4 cm. by 2 cm. by 1 cm."

(5) *Does any Form of Biopsy Permit us to Watch Sufficiently the Evolution of a Tumour and to Establish its Nature?*

Biopsy is unlikely to be considered until one or two months have elapsed since the onset of the lesion. During this interval, though there may be little clinical and no radiographic evidence of bone involvement, considerable changes can occur in the tissues, the inception and nature of which the histologist appears to be unable to divine from the material taken after the interval. In the second case cited, S. L. Baker [6], though fortunate enough to have clinical and radiographic evidence of a definite fracture but five weeks previously, was unable to indicate the true nature of the lesion. He regarded the abnormal tissue in the first instance as that of chondrosarcoma and later (owing to the good fortune of the child being too ill for disarticulation at the hip-joint), when resolution was obviously occurring, as hyperplastic callus, which he stated at a recent meeting began with the deposition of woven bone. Commenting in his paper on a previous report of the author's on four such cases he states: "I have been unable to find any detailed account of a closely similar case in the literature. Brailsford (1943), however, gives an account of the radiographic appearances of four cases of osteogenesis imperfecta in which masses of bone were found in relation

of simple nature. It certainly introduces the definite factor of trauma, the results of which may seriously affect and confuse the radiological, clinical and histological picture. Hence it was thought that tumour tissue could be removed with the minimum trauma by needle puncture biopsy.

(4) *Why "Real" Biopsy?*

Because it was thought that needle biopsy or mere incision into the tumour and removal of a small portion did not provide adequate material for diagnosis. Indeed, in the "Recent Advances in Clinical Pathology", 1947, speaking in support of aspiration biopsy, Hermitte and Ellis make the following statement: "Failure to obtain any tissue is of little significance, and failure to obtain pathological material does not rule out the presence of a lesion. It is in fact the rule in the case of hard lesions, such as fibromas, and well-differentiated bony osteogenic sarcomas. It is worth remembering, however, that a negative result, in cases such as those mentioned, far from being devoid of meaning, may indeed be considered as evidence in favour of a reasonably confident clinical diagnosis." The reports on the small fragments of tissue often resulted in erroneous opinions being given. It was thought that extensive exposure of the tumour permitted the surgeon to obtain adequate pieces of tumour from several sites which he regarded as likely to supply the essential evidence, and J. S. Young [7] had expressed his opinion that incision into the tumour bone would release the tension which possibly results in the expulsion of tumour cells into the vessels.

But even when the whole tumour is resected or the affected limb amputated, permitting the pathologist to cut out sections where he will, we still have the experience of erroneous interpretation of well-established lesions; sometimes malignant lesions being described as simple, sometimes simple described as malignant.

The histories of the following two cases illustrate these errors. Details of the first case are as follows (notes supplied to author from case history):

"The patient, K. P., a young woman aged 20, attended hospital complaining of progressively increasing pain in the lateral aspect of the right knee-joint—a site in which she had noticed a swelling which had steadily increased in size during the past two years. She could give no history of injury or strain to the area. No abnormal features were detected in the clinical history or examination apart from this.

"On examination the right knee appeared to be swollen on the outer side. On palpation a bony swelling was felt on the lateral aspect of the lateral femoral condyle which was about 3 in. long and 2 in. wide reaching to the lateral edge of the patella. The surface was smooth and edges were obscured by soft tissue. The mass appeared to be attached to the bone but not to the skin. Tenderness was present at one point only about the centre of the mass. There was no free fluid in the knee-joint and though flexion was limited to 90 degrees the other movements were full. The inguinal glands showed no enlargement. Radiographs, 12.7.46, showed a large mass of calcification situated on the posterior and external surfaces of the lower third of the femur. The bone does not appear to be eroded at any place and shows a well-marked line of demarcation. The nature of the lesion is uncertain but it would not appear to be a bone sarcoma. The possibilities are myositis ossificans or chronic inflammation and a simple bone tumour. No lesion revealed in the chest or other bones by radiography.

"October 12, 1946: The radiographs were sent to Dr. James F. Brailsford, Birmingham, for his opinion, and his report dated October 13, 1946, reads: 'I am of the opinion that this is a chondrosarcoma of relatively slow growth. The characters and clinical features are against your suggestion of melorheostosis.'

"4.11.46: *Operation (1st)*.—Biopsy of bone tumour. Specimen sent to Edinburgh for examination and report.

"21.11.46 (Report on biopsy material): 'No evidence of malignancy and no evidence of osteogenic sarcoma. I do not know what all these appearances mean in terms of cell metabolism but since this was a tumour I think it can only be a chondroma which is undergoing ossification. I have shown the slide to Professor Flanery who confirms that there is no evidence of sarcoma and agrees that ossifying chondroma is the most reasonable histological diagnosis.'

"25.11.46: *Operation (2nd)*.—All the tumour removed as far as possible.

"8.1.47 (Pathologist's report): 'Microscopic sections show cancellous bone with widened inter-

(6) *Does Prompt Amputation Ensure Cure?*

We have no definite evidence that it does. We have evidence that following amputation of limbs because of lesions thought to be sarcomatous, the patients suffer no recurrence, but as I have illustrated [10] with a number of cases the clinical and radiographic features may be judged to be those of sarcoma yet the real proof that they are not was given in the complete resolution of the lesions and restoration to normal health—amputation being put out of the question by the serious condition of the patients at the time. This clinical evidence is surely better evidence than histology of the nature of the lesion, for have we not the evidence of S. L. Baker's [6] case of a hæmatoma mistaken for sarcoma from the clinical, histological and radiographic evidence and his statement that: "Had the leg been removed in my Case 1 it would have been impossible to prove that it was not a sarcoma cured by amputation."

I have previously recorded two cases in which erroneous interpretation of histological material may have ended in disaster (*Proc. R. Soc. Med.*, 1947, 40, 787).

In another early case where I was satisfied from previous experience that the lesion was a sclerosing osteogenic sarcoma and that there were no indications of metastases in the lungs or other bones from the radiographic appearances, I advised prompt amputation [12]. This was performed by A. M. Hendry without any preliminary trauma or biopsy. The patient rapidly recovered from the operation, but in little over a year she had hæmoptyses, and radiography showed multiple metastases from which she died within a few weeks. Though radiographs are taken of the lungs or skeleton (metastases from osteogenic sarcoma often develop in other parts of the skeleton before they are recognizable in the lungs; the latter being a terminal event) and fail to reveal any evidence of metastases, this is no proof that they do not exist; they have to grow to a sufficient size or produce sufficient contrast density or destruction, before visualization by radiography is possible—the latent negative radiographic period [17]. This may be as long as a year or more, but may be within one or two weeks. As John Hunter observed: "To amputate is to mutilate a patient we cannot cure. It should therefore be considered as an acknowledgment of the imperfection of our art." Though amputation does not ensure cure it removes all chance of investigating the nature of the lesion and its response to various forms of treatment, i.e. it contributes nothing to our knowledge of bone tumours.

(7) *Will Biopsy Enable Us to Get an Early Diagnosis?*

We have seen from the histories of the cases cited that the evidence supplied by biopsy may indicate simplicity when the lesion is malignant or indicate malignancy when the lesion is simple, and that prompt amputation in early cases with little or no reliable signs may prove to be unjustifiable, yet when the evidence of histology is reported as simple great delay may result, as in the first case cited. Though in this case the radiographs permitted the diagnosis of malignancy to be made the patient was submitted to four surgical operations and a delay of seven months because the evidence provided by biopsy, and later extensive resection, was of a simple tumour.

(8) *If the Histology is Reported as Indicating Malignancy Would the Surgeon Promptly Amputate a Limb for an Early Lesion which on Clinical and Radiographic Grounds is Uncertain? If he Would Not, What Can Justify the Surgery of Biopsy?*

Amputation would result in the destruction of limbs for many simple lesions, which, as I have shown [10], left alone, would resolve. Even when the evidence of clinical, radiographic and histological examinations has been interpreted as indicating a malignant tumour, it has been found that the lesion was simple; see cases cited under question 6.

(9) *Does the Evidence of Trauma Assist in Diagnosis or Influence Biopsy?*

It does and it should. The author makes it a rule to regard any lesion as simple in the first instance if there is definite evidence of trauma and the radiographic evidence

to the femur. He gives an illustration of the X-ray appearances of one of these showing involvement of the lower two-thirds of both femurs in masses of spongy bone very similar to the end-result seen in Case 1 here reported. He assumes that this condition resulted from subperiosteal hæmorrhages produced by scurvy, but the evidence for this conclusion appears very scanty, and the right femur shows a bend suggesting an old fracture in the lower third of the shaft and also an irregular mass of bone extending into the soft tissues from the upper half of the shaft. One of the other three cases he mentions was a boy of 14 years who showed a cancellous mass extending from the lesser trochanter down the whole length of the diaphysis of the right femur. This developed after a contusion of the thigh seven years previously. It appears to me that all four of Brailsford's cases may well have been traumatic in origin, with, quite possibly, incomplete fractures which passed unnoticed at the time. In one of these four cases Brailsford noted that there was also a mass on the lower end of the right tibia and that this underwent a rapid increase in size and showed evidence of malignant metaplasia; it may have been a rapid callus production following trauma to the masses." The evidence of malignant metaplasia in the one case was a change in the radiographic appearances and death later with metastases.

Unfortunately Baker did not seek further information respecting my cases before he published his paper, which was not seen by me until it was brought to my attention by a colleague some months after. I could then have indicated that though infantile scurvy is usually regarded by the authorities as a deficiency disease which shows itself between the eighth and twelfth month, I have seen instances of infants within the first three months of life with large hæmatomata enveloping the whole of one or more diaphyses which began to improve immediately, clinically and radiographically, on the administration of vitamin C and maintained freedom from recurrence. There is no necessity for the trauma to be of such severity that fracture is produced to cause a hæmatoma, though in osteogenesis imperfecta fracture may occur merely from turning over in bed. That the initial lesion was hæmatoma and not deposits of woven bone is supported by R. Hutchison and A. Moncrieff [9] who have pointed out that "the chief changes (in infantile scurvy) are in the neighbourhood of the bones. A section made across a limb at the site of a swelling shows that the periosteum is hypervascular, thickened and separated from the subjacent bone by a layer of partially organized blood clot. There is no sign of inflammation and no hard bone is formed in the periosteum, except in long-standing cases". In one case seen by the author there was radiographic evidence that the hæmatoma, which when seen first when the child was 3 months old, contained a deposit of amorphous calcium, had begun to ossify within one month of the regular administration of vitamin C.

Repeated biopsies are likely to lead to further confusion, for added to the initial lesion you have the effects which have resulted from the surgical trauma some weeks or months previously. Though "real biopsy" may permit of macroscopic examination of some aspects of the tumour, but not all, such extensive inspection would hardly be reasonable, or even possible, at the subsequent operations and the material provided for histological examinations can be but a microscopic portion of the whole tumour; and even when multiple sections are taken they may not include the features essential for accurate diagnosis, and do not permit of visualization of the tumour as a whole, or permit us to watch its development—facts which are well illustrated by S. L. Baker's case [6].

Ossifying hæmatomata, not only in scurvy and osteogenesis imperfecta, but also in limbs with neurovascular disturbances and in hæmophilia, and even at the site of unsuspected fractures, have been mistaken on their clinical and histological evidence as sarcomata and amputation has resulted when the patients were considered to be fit enough to stand the operation. Undoubtedly some of these cases are regarded as "cures by amputation".

(6) *Does Prompt Amputation Ensure Cure?*

We have no definite evidence that it does. We have evidence that following amputation of limbs because of lesions thought to be sarcomatous, the patients suffer no recurrence, but as I have illustrated [10] with a number of cases the clinical and radiographic features may be judged to be those of sarcoma yet the real proof that they are not was given in the complete resolution of the lesions and restoration to normal health—amputation being put out of the question by the serious condition of the patients at the time. This clinical evidence is surely better evidence than histology of the nature of the lesion, for have we not the evidence of S. L. Baker's [6] case of a hæmatoma mistaken for sarcoma from the clinical, histological and radiographic evidence and his statement that: "Had the leg been removed in my Case 1 it would have been impossible to prove that it was not a sarcoma cured by amputation."

I have previously recorded two cases in which erroneous interpretation of histological material may have ended in disaster (*Proc. R. Soc. Med.*, 1947, 40, 787).

In another early case where I was satisfied from previous experience that the lesion was a sclerosing osteogenic sarcoma and that there were no indications of metastases in the lungs or other bones from the radiographic appearances, I advised prompt amputation [12]. This was performed by A. M. Hendry without any preliminary trauma or biopsy. The patient rapidly recovered from the operation, but in little over a year she had hæmoptyses, and radiography showed multiple metastases from which she died within a few weeks. Though radiographs are taken of the lungs or skeleton (metastases from osteogenic sarcoma often develop in other parts of the skeleton before they are recognizable in the lungs; the latter being a terminal event) and fail to reveal any evidence of metastases, this is no proof that they do not exist; they have to grow to a sufficient size or produce sufficient contrast density or destruction, before visualization by radiography is possible—the latent negative radiographic period [17]. This may be as long as a year or more, but may be within one or two weeks. As John Hunter observed: "To amputate is to mutilate a patient we cannot cure. It should therefore be considered as an acknowledgment of the imperfection of our art." Though amputation does not ensure cure it removes all chance of investigating the nature of the lesion and its response to various forms of treatment, i.e. it contributes nothing to our knowledge of bone tumours.

(7) *Will Biopsy Enable Us to Get an Early Diagnosis?*

We have seen from the histories of the cases cited that the evidence supplied by biopsy may indicate simplicity when the lesion is malignant or indicate malignancy when the lesion is simple, and that prompt amputation in early cases with little or no reliable signs may prove to be unjustifiable, yet when the evidence of histology is reported as simple great delay may result, as in the first case cited. Though in this case the radiographs permitted the diagnosis of malignancy to be made the patient was submitted to four surgical operations and a delay of seven months because the evidence provided by biopsy, and later extensive resection, was of a simple tumour.

(8) *If the Histology is Reported as Indicating Malignancy Would the Surgeon Promptly Amputate a Limb for an Early Lesion which on Clinical and Radiographic Grounds is Uncertain? If he Would Not, What Can Justify the Surgery of Biopsy?*

Amputation would result in the destruction of limbs for many simple lesions, which, as I have shown [10], left alone, would resolve. Even when the evidence of clinical, radiographic and histological examinations has been interpreted as indicating a malignant tumour, it has been found that the lesion was simple; see cases cited under question 6.

(9) *Does the Evidence of Trauma Assist in Diagnosis or Influence Biopsy?*

It does and it should. The author makes it a rule to regard any lesion as simple in the first instance if there is definite evidence of trauma and the radiographic evidence

to the femur. He gives an illustration of the X-ray appearances of one of these showing involvement of the lower two-thirds of both femurs in masses of spongy bone very similar to the end-result seen in Case 1 here reported. He assumes that this condition resulted from subperiosteal hæmorrhages produced by scurvy, but the evidence for this conclusion appears very scanty, and the right femur shows a bend suggesting an old fracture in the lower third of the shaft and also an irregular mass of bone extending into the soft tissues from the upper half of the shaft. One of the other three cases he mentions was a boy of 14 years who showed a cancellous mass extending from the lesser trochanter down the whole length of the diaphysis of the right femur. This developed after a contusion of the thigh seven years previously. It appears to me that all four of Brailsford's cases may well have been traumatic in origin, with, quite possibly, incomplete fractures which passed unnoticed at the time. In one of these four cases Brailsford noted that there was also a mass on the lower end of the right tibia and that this underwent a rapid increase in size and showed evidence of malignant metaplasia; it may have been a rapid callus production following trauma to the masses." The evidence of malignant metaplasia in the one case was a change in the radiographic appearances and death later with metastases.

Unfortunately Baker did not seek further information respecting my cases before he published his paper, which was not seen by me until it was brought to my attention by a colleague some months after. I could then have indicated that though infantile scurvy is usually regarded by the authorities as a deficiency disease which shows itself between the eighth and twelfth month, I have seen instances of infants within the first three months of life with large hæmatomata enveloping the whole of one or more diaphyses which began to improve immediately, clinically and radiographically, on the administration of vitamin C and maintained freedom from recurrence. There is no necessity for the trauma to be of such severity that fracture is produced to cause a hæmatoma, though in osteogenesis imperfecta fracture may occur merely from turning over in bed. That the initial lesion was hæmatoma and not deposits of woven bone is supported by R. Hutchison and A. Moncrieff [9] who have pointed out that "the chief changes (in infantile scurvy) are in the neighbourhood of the bones. A section made across a limb at the site of a swelling shows that the periosteum is hypervascular, thickened and separated from the subjacent bone by a layer of partially organized blood clot. There is no sign of inflammation and no hard bone is formed in the periosteum, except in long-standing cases". In one case seen by the author there was radiographic evidence that the hæmatoma, which when seen first when the child was 3 months old, contained a deposit of amorphous calcium, had begun to ossify within one month of the regular administration of vitamin C.

Repeated biopsies are likely to lead to further confusion, for added to the initial lesion you have the effects which have resulted from the surgical trauma some weeks or months previously. Though "real biopsy" may permit of macroscopic examination of some aspects of the tumour, but not all, such extensive inspection would hardly be reasonable, or even possible, at the subsequent operations and the material provided for histological examinations can be but a microscopic portion of the whole tumour; and even when multiple sections are taken they may not include the features essential for accurate diagnosis, and do not permit of visualization of the tumour as a whole, or permit us to watch its development—facts which are well illustrated by S. L. Baker's case [6].

Ossifying hæmatomata, not only in scurvy and osteogenesis imperfecta, but also in limbs with neurovascular disturbances and in hæmophilia, and even at the site of unsuspected fractures, have been mistaken on their clinical and histological evidence as sarcomata and amputation has resulted when the patients were considered to be fit enough to stand the operation. Undoubtedly some of these cases are regarded as "cures by amputation".

which are essentially different. Not all observers are sufficiently careful in describing what they see. Unfortunately it happens that these erroneous interpretations are the ones which often attract interest, and later writers, perhaps equally careless, apply such descriptions to material of their own, so that we ultimately get lesions described which are totally different from those in the original work. The author has successfully established the erroneous interpretations recorded in several such cases in others. However, criticism of such accounts is difficult because it may be felt that all the facts have not been included.

RADIOLOGY

With the unsatisfactory nature of the evidence provided by biopsy we must turn elsewhere for better evidence and I believe that this is being supplied with increasing accuracy by radiology.

John Hunter observed: "It is astonishing to see what little curiosity people have to observe the operations of Nature and how very curious they are about the operations of art," though he had not the advantage of radiological examination by which it is possible to watch the changes taking place in the tumour and the bone in which it is growing. We have seen that there is little to be gained by precipitate amputation, but something is to be gained by observation over a period when the radiographic evidence at the first examination is not conclusive. As soon as Roentgen's discovery was made known to the world it was hailed by the medical and lay press as a means of examination which could be done without causing the patient pain. Radiology contributes its greatest help in the diagnosis of bone tumours when used in this way. Unfortunately instead of using X-rays in this way, watching the development of lesions, and learning the time-table of the changes in their radiographic appearances, there has been an incitement to biopsy, a tendency to seek a rapid explanation for the radiographic appearances, particularly when they are spectacular, by biopsy. This as we have seen inflicts pain and risk without necessarily contributing any useful additional information and often providing confusing evidence and complications. It is this outlook which entices the enthusiast, the thoughtless, and the inexperienced, to cut into the tissues of a patient who is already suffering from a lesion which clinically and radiographically is inoperable—a procedure which cannot reasonably be justified. It is amazing how some of these apparently inoperable lesions will completely resolve when surgery is considered and left quite out of the question; meddlesome interference often obscures the issue, delays resolution, and may prevent complete restitution. I have shown in my book [14] that radiographic appearances of most bone tumours are characteristic and permit of classification but the evidence is not self-explanatory. The significances of the appearances can, like all other studies, only be appreciated fully by those who are prepared to spend the time in acquiring a knowledge of every possible change which can occur in bones and joints, and even when they have done this for many years, they will still be faced, in a big hospital department, with some problem every week. It is because this is not appreciated, even in teaching schools, that we so often see accounts of some simple lesion "simulating sarcoma". These cases will grow less and less as we learn more and more of the characters in radiographic appearances.

In a previous paper (*Proc. R. Soc. Med.*, 1947, 40, 787) reference is made to the opposing indications of radiography and histology illustrated by Geschickter and Copeland.

While it is appreciated by many that before we can detect the early signs of pathology we must have a very searching knowledge of the normal, it is not quite so well appreciated that all the many simple changes in bones and joints must be known before we can hope to distinguish successfully the simple from malignant. Serial radiographic studies of all lesions permit us to draw up a time-table of changes and the knowledge,

is such as could have been produced by the trauma. Obviously this demands a knowledge of the time-table of radiographic evidence of bone lesions and the ability to assess whether the bone was normal at the time of the injury. The development of a sarcoma at the site of a recent trauma, and as the result of that trauma, is very, very rare. I have never seen one (I have seen but two genuine sarcomata arising at the site of old bone injuries. In both cases I reported only the evidence of old fractures—gun-shot wounds several years old—the evidence of malignant metaplasia was indicated by the clinical appearances). Because of this and the experience with biopsy I always advise that lesions with a history of recent trauma and radiographic evidence of changes which could have been produced by that trauma should be treated with medicaments as inflammatory, notwithstanding certain radiographic features which may arouse the suspicion of malignancy. I also advise “no biopsy” for the reasons already stated. In the case of S. L. Baker’s [6] Case 1 the clinical and radiographic evidence of recent fracture should have prohibited the biopsy which was made but five weeks after the fracture. Alas! it did not, and though the subsequent radiographs he used to illustrate his paper showed great extension of the enveloping femoral hæmorrhage due to the surgery, this did not prevent similar disastrous surgery in his Case 2. The catastrophes which may follow erroneous interpretation of malignancy in such cases should warn any surgeon against biopsy.

(10) *Does Biopsy Permit Us to Describe Cases as “Fully Proven”?*

The answer to question 6 suggests that it does not. This is supported by the photograph fig. 2A and radiograph fig. 2B of H. Platt’s cases. The radiograph 2B shows an osteolytic lesion of the upper end of the tibial diaphysis with involvement of the epiphysis (the growth cartilage commonly acts as a barrier to sarcoma) but these clinical and radiographic appearances, though highly suspicious, are no more typical than in the cases which I have recorded which completely resolved without any surgery; and we have the support of his subsequent findings, that this boy is living and well ten years after operation.

Meyerding [5], an advocate of biopsy, goes as far as to state “that even though microscopic section and examination, and roentgenographic examinations are employed, the true characters of the lesion may not be known until *metastases and death have occurred*”.

It is interesting to note that in his 161 cases of sarcomata Platt has no five-year cure from a sclerosing sarcoma and but 4 with a survival of less than two years, yet Geschickter and Copeland [13] claim 17 cures in 65 cases. They state “the chances of cure are more than 25%, when primary radical operation is performed”. It was a sclerosing sarcoma which recurred though prompt amputation followed early diagnosis, see answer to question 6.

(11) *Has Everything Else Been Done to Determine the Nature of the Tumour?*

One thing is certain. Before we seek the help of the pathologist we must make a thorough investigation into the clinical history, signs and symptoms, using all the necessary clinical methods for the detection of sepsis, syphilis and other inflammatory and blood disorders. Though the information obtained in this way may not in itself permit us to determine whether the lesion is simple or malignant, it often gives us an important clue to the diagnosis. It may indicate the directions in which further investigations should be made, or, combined with the radiographic appearances, permit of accurate diagnosis.

There is very great need to scrutinize cases reported in the literature. This particularly applies to reports on groups of cases, for in the enthusiasm to swell the numbers reported on, or to add to some recently discovered signs, cases are included

is indefinite, is erroneous; actually it may directly and indirectly add conflicting evidence which will delay the accurate diagnosis.

Ultimate resolution of a bone tumour which had clinical and radiographic (and even histological) appearances of malignancy is the best evidence of simplicity or removal of the destructive influence. In view of the not uncommon occurrence of such cases, it is unjustifiable to record lesions as "fully proven" malignant tumours, though the clinical, histological (and perhaps the radiographic), appearances suggested malignancy, if amputation results in cure.

A malignant bone tumour, like a gumma, appears to indicate a local expression of a constitutional disturbance, which may completely disappear when the patient is given the essential corrective; for in spite of the earliest amputation similar lesions (? metastases) may develop at any time after, even with twenty years' symptomless interval. Yet as the author has illustrated [10] primary lesions and the multiple associated lesions which have the features of metastases may resolve completely or sufficiently to permit of the average duration of symptomless normal life, i.e. not just an extended existence, which too often is unrecorded in the accounts of two to five year cures. The remarkable response of carcinomatous metastases from some primaries in the breast or prostate to stilboestrol within a few weeks gives us the hope that some such hormone will be found to cure sarcoma.

RECOMMENDATIONS

In the investigation of any bone tumour a careful study of the clinical history and condition of the patient should be made, paying particular attention to any hereditary dysplasia or dystrophy, the possibility of any vitamin deficiency, endocrine or blood disorder, infection or trauma.

A careful radiographic examination should be made of the lesion, of the lungs and any other part of the body which on examination or report is abnormal.

If the radiographic appearances indicate a simple lesion the appropriate treatment should be given.

If the lesion has the radiographic features which suggest malignancy the only treatment which our present imperfect knowledge dictates is amputation. This is an irrevocable procedure, the success of which cannot be predetermined, for we have no means of ascertaining how extensive or widespread the disorder, or knowledge of what can influence it. Consequently as the radiographic appearances can be closely mimicked by inflammatory or deficiency and other disorders, in any doubtful case it would be reasonable to give a course of appropriate medication, and if this fails to produce a favourable response, a course of deep X-radiation therapy. Though Platt has stated: "Irradiation is admittedly a useless form of therapy in tumours of the osteogenic sarcoma group" since the author has shown that some tumours which are indistinguishable from this group completely resolve following X-radiation, the latter is worth a trial. Even when it is established beyond all reasonable doubt that the tumour is malignant and amputation is decided upon, there appears to be some justification in preceding this with a full sarcoma dose of X-rays in a short time, since the radiographic indications of malignancy in certain tumours often disappear for a period following X-radiation therapy [11]—evidence which suggests the possibility of some degree of localization.

Under the auspices of the American College of Surgeons, a Registry of Sarcoma was set up, which included such competent authorities as surgeons, physicians, pathologists, and radiologists. Such a body examines material submitted and attempts to classify the tumours and record the results of treatment. Such a body is necessary where the material is widespread yet locally relatively rare. The author in 1936 [15]

obtained without causing the patient any pain, will permit of more accurate diagnosis and better treatment of the patient.

Not the least value of radiography is its use in watching the progress of a lesion after the exhibition of chemical and physical agents. The response seen by radiography to follow antisyphilitic medication is a better indication of the nature of the lesion than can be obtained by the Wassermann reaction.

If radiology is to hold the place which I believe it deserves to hold, radiologists must shoulder the responsibility, though this will cause the loss of many winks of sleep, but their loss may be rewarded by the desire to possess a sounder knowledge of radiology. Too often in the past have reports been inconclusive, trusting that a biopsy will be made which would supply evidence agreeing with one of the tentative suggestions made and giving the clinician little or no guidance in treatment on which he can rely. It is frequently said that there are few radiologists who can give a reliable opinion on bone tumours and this is why reference is made to biopsy, but I am convinced that the histological evidence is at least equally unreliable and it falls far shorter because it does not permit of visualization of the whole tumour or permit of repeated observations during its growth and treatment. A summation of unreliable reports does not ensure accuracy. While the surgeon, faced with the problem of what to do after making the diagnosis of a sarcoma, sometimes on inadequate evidence or knowledge, either amputates the limb or takes refuge in the transference to his colleague, the radiotherapist, the latter appears to accept as final the report on the biopsy and administers his doses hopefully but not necessarily wisely. More careful clinical and radiological investigation of these cases will reduce the number of cases cured by amputation to the advantage of the patients.

CONCLUSIONS

The essential point to establish in the diagnosis of a bone tumour is whether it is simple or malignant. Attempts at classification on histological appearances are of academic rather than of practical importance—they tend to cause erroneous interpretation. Certain simple lesions, which undisturbed completely resolve, have histological appearances liable to be erroneously interpreted as evidence of malignancy; yet this evidence cannot be obtained without biopsy or more extensive surgery. This cannot be done without causing the patient mental and physical pain, or without subjecting the patient to the risks of an anæsthetic, complications, and the possibility of erroneous interpretations. Though there are certain histological features which appear to indicate malignancy, these features are frequently not found in malignant tumours and the erroneous interpretation of simplicity is made.

The radiographic appearances of bone tumours are infinite and consequently not self-explanatory. The simple lesions have characteristic radiographic appearances which can be verified by serial radiography without causing the patients pain or subjecting them to any risks. The malignant tumours have certain characteristic features also, but their identification necessitates a knowledge of the infinite varieties of the normal and the simple lesions, because these features are mimicked by certain simple lesions. Fortunately the diagnosis can be checked during an interval of careful clinical observation and serial radiography.

Since amputation at the earliest possible moment does not ensure cure of a malignant tumour, and since we have no means of telling whether metastasis has occurred (the radiographic visualization necessitates a long latent period [12]), there is little to be gained by precipitate amputation, but much to be gained by clinical and radiographic study. The supposition that biopsy will permit the surgeon to establish the nature of a lesion, which clinically and radiographically to competent observers

DISCUSSION ON THE ELECTRO-ENCEPHALOGRAM IN ORGANIC CEREBRAL DISEASE

Dr. W. Grey Walter: Electro-encephalography has been used for about ten years to help in the diagnosis and prognosis of cerebral disease. The advances which have been made in that time are really rather disappointing, but during the war years the rate of progress was slow, though the number of centres increased in all countries.

For the purposes of this discussion the subject may be divided into three parts. First I should like to mention the technical advances which have been made and are now in progress, with particular reference to their value in studying organic conditions. Secondly, I propose to enumerate the empirical findings which are generally supposed to suggest the presence of organic pathology. Thirdly, it may be of interest to scan the methods which are now being developed to extend the scope of the subject.

The basic technical device which has been generally adopted is the employment of multi-channel direct recording instruments, with soundly planned bipolar electrode placements. The general acceptance of this technique is embodied in the recommendations drawn up in this country, in the United States and, more recently, by the International E.E.G. Committee.

In the early days of electro-encephalography, few centres used more than three channels of recording. Nowadays six is the preferred number; some centres use eight and one or two as many as twelve. It is generally agreed that the use of more than six recorders puts a great strain both on finance and on the interpretative ability of the recordist. For this reason a logical development has recently been introduced which can employ several score of channels without burdening the operator with yards of record. This device, which has been called a "Toposcope", exploits the fact that for certain purposes the information required about the patient is more a matter of topographic detail than of changes with respect to time. Accordingly, the electrical activity of the brain is displayed upon a cathode-ray oscilloscope of large diameter in such a way that the regions where electrical activity is in progress can be directly observed as a flickering light, giving the illusion that the observer is looking at the head of the patient and can see the significant discharges where they are actually occurring.

suggested that this should be done in this country. Since then the British Orthopaedic Association made a tentative effort at this but as the Association did not seek the co-operation of general surgeons, pathologists or radiologists its efforts were bound to be ineffective. More recently the Royal College of Surgeons has set up a Registry, but as it appears to base its findings essentially on the clinical and histological appearances without the co-operation of those physicians and radiologists who have studied the problem, it cannot meet with the success which is so desirable. It may provide much material for the museum but lesions so extensively developed that amputation was performed are unlikely to provide much evidence which will assist in what we most desire, i.e. early diagnosis. The pathological museums of the world contain many hundreds of such specimens but they have not materially helped us to make an early diagnosis. Many of the tumours will be from patients who have been subjected to medication, X-radiation, surgical trauma, &c., and these factors acting over a variable time would have had an influence on the histological appearances which cannot be estimated. Though some satisfaction may be felt in contributing specimens to the museum, a greater satisfaction is felt when a lesion completely resolves which had the clinical, radiographic, and even the histological features of malignancy. What we need is a central court of reference which invites full co-operation to which the available evidence of doubtful cases can be submitted for diagnosis before surgery, for from it we may derive the greater satisfaction. In considering the histological classification of any specimen of an amputated limb it would always be well to bear in mind the words of S. L. Baker on a lesion which was proved radiographically and clinically to be an ossifying hæmatoma: "Had the leg been removed in my Case 1 it would have been impossible to prove that it was not a sarcoma cured by amputation".

My thanks are due to the many colleagues who have submitted cases to me and in this instance particularly to Dr. Patricia Franklyn, Dr. Whateley Davidson, the medical staff of the Royal Cripples Hospital, and the members of the X-ray staff for supplying radiographs and case-histories from which the evidence presented has been obtained.

DISCUSSION ON THE ELECTRO-ENCEPHALOGRAM IN ORGANIC CEREBRAL DISEASE

Dr. W. Grey Walter: Electro-encephalography has been used for about ten years to help in the diagnosis and prognosis of cerebral disease. The advances which have been made in that time are really rather disappointing, but during the war years the rate of progress was slow, though the number of centres increased in all countries.

For the purposes of this discussion the subject may be divided into three parts. First I should like to mention the technical advances which have been made and are now in progress, with particular reference to their value in studying organic conditions. Secondly, I propose to enumerate the empirical findings which are generally supposed to suggest the presence of organic pathology. Thirdly, it may be of interest to scan the methods which are now being developed to extend the scope of the subject.

The basic technical device which has been generally adopted is the employment of multi-channel direct recording instruments, with soundly planned bipolar electrode placements. The general acceptance of this technique is embodied in the recommendations drawn up in this country, in the United States and, more recently, by the International E.E.G. Committee.

In the early days of electro-encephalography, few centres used more than three channels of recording. Nowadays six is the preferred number; some centres use eight and one or two as many as twelve. It is generally agreed that the use of more than six recorders puts a great strain both on finance and on the interpretative ability of the recordist. For this reason a logical development has recently been introduced which can employ several score of channels without burdening the operator with yards of record. This device, which has been called a "Toposcope", exploits the fact that for certain purposes the information required about the patient is more a matter of topographic detail than of changes with respect to time. Accordingly, the electrical activity of the brain is displayed upon a cathode-ray oscilloscope of large diameter in such a way that the regions where electrical activity is in progress can be directly observed as a flickering light, giving the illusion that the observer is looking at the head of the patient and can see the significant discharges where they are actually occurring.

Another type of technical refinement is the automatic analysis of the records in terms of their various components, in the form of a frequency spectrum. This device is now fairly familiar. Its function is merely to assist the interpreter by disclosing components invisible to the naked eye and to provide quantitative information, where previously only qualitative descriptions were available. Automatic frequency analysis can be combined with toposcopy in such a way that the local activity of quite small cell groups can be detected and measured, and the anatomical dissemination or suppression of the various modes of activity can be quite accurately traced. This type of study is of particular value in organic conditions, as compared with, for example, cases of epilepsy, since there is less danger of overlooking transient or paroxysmal changes, which are still best studied by means of the conventional multi-channel recorder.

One of the most healthy signs in electro-encephalography is the tendency to include on the record a registration of other variables beside the E.E.G. itself, and thus, respiration, electrocardiogram, blood-pressure, skin resistance, muscular activity and so forth appear more and more frequently in electro-encephalographic tracings, so that the correlation of nervous and somatic perturbations can be more readily made.

The limitation imposed on ordinary electro-encephalography by having to record through the unopened skull is still serious. There is still no trustworthy method of distinguishing between cortical and basal activity, but the use of special electrode designs and placements has produced some promising results. The bipolar nasal or pharyngeal electrode provides at least a different approach to the basal structures, though these still remain relatively inaccessible to the electro-physiologist. When direct access can be obtained to the brain through a burr-hole or during an operation, both the cortex and the deeper structures can be explored with no more damage than is caused by the ordinary brain needle, which can be converted into a satisfactory bipolar electrode of small dimensions. Naturally, opportunities for such observations occur only in cases where organic disease is suspected, so that information on entirely normal human brains has not been obtained in this way, but in many cases the abnormal region occupies only part of the operative field so that direct comparisons of healthy and disturbed function can be made at all cerebral levels. Apart from the physiological interest of such data, the precise delimitation of subcortical new growth and abscess formations has been found of considerable practical value. This procedure, at least, requires only the simplest recording equipment and can be combined with the withdrawal of specimens for biopsy.

One may anticipate that valuable observations may be made in the future by combining the technique of direct exploration with the experimental procedures to be discussed later.

We may now turn to the enumeration of those features of the electro-encephalogram which are suggestive of organic pathology. It may be best to consider them, at first, quite empirically, in order to outline the scale of variation. First of all there are the classical slow rhythms which were originally called "delta" waves. A summary of the facts relating to these is contained in Table I. It will be seen that great care is necessary in interpreting records containing only this type of abnormal activity, particularly when the diagnosis lies between an organic condition and one of, for example, idiopathic epilepsy. The data summarized under the heading "Wave-form" are of the greatest importance, since it is the irregularity and variability of the discharges which seem to suggest an acquired lesion. It is tempting to suppose that this irregularity is due to the presence of many independent components, as suggested by the frequency analysis, for this would fit in well with the conception that the lesion

is producing a condition of what one might call "forced oscillation" on the part of the cell-groups near-by. One may, perhaps, consider this irregular polyrhythmic delta discharge as a strictly pathological phenomenon, at any rate when it is focal or limited in its extent. Its resemblance to the activity seen in deep sleep and in infants suggests a further speculation about the function, if any, of such slow rhythms. It is never satisfactory to regard a phenomenon as without significance and some years ago it was suggested that slow activity of this type may represent the activity of a mechanism whereby neurones are relieved of their normal function in disturbed conditions, thus taking the place in the brain which pain does in most other parts of the body. If this is really the function of slow activity in these conditions, one might expect that the imposition of slowly changing electrical currents on the brain from

TABLE I.—ABNORMAL E.E.G. FEATURES SUGGESTIVE OF ORGANIC PATHOLOGY

SLOW (delta, 0.5 to 3.5 c/s).

Amplitude: The larger the amplitude the greater the area involved.

Frequency: The lower the frequency the more acute and/or rapidly progressive the lesion. ("Sub-delta" 0.2 to 1 c/s characteristic of acute abscess.)

Wave-form: Irregular, polyrhythmic, non-harmonic (e.g. 1.5 + 2.5 c/s) near lesion. Monorhythmic, or harmonic in homologous area of opposite hemisphere or bilateral when lesion is deep.

Persistence: Persistent near lesion, paroxysmal and/or responsive in homologous or bilateral foci.

Topography: Diffuse resembles sleep and infancy, otherwise suggests raised intracranial pressure, toxic conditions. Focal good evidence of local pathology in all cases, but lesion often posterior to focus.

GENERAL SIGNIFICANCE

Cortical involvement when polyrhythmic and persistent.

outside might have a similar effect and I have personally experienced that this is, in fact, the case; when a current of about 20 milliamps fluctuating at one or two cycles per second is passed through the head by means of electrodes of the conventional E.E.G. type, a drowsy and inattentive state of mind can be induced. These experiments are still incomplete but it would certainly be a relief to assign a specific function to the slow activity, so useful to the electro-encephalographer. It is worth noting, also, that as well as delta activity from the neighbourhood of a region of a cortical lesion, more rhythmic delta waves are often seen from remote regions; this type of disturbance often resembles the normal spontaneous rhythms in being responsive to physiological stimulation, and seems to follow the normal anatomical pathways. For this reason it has been called "quasi-physiological" and it often gives a most valuable clue to the extent of the lesion itself: sometimes, at least, it is associated with recent interference with certain anatomical circuits and commissures.

Table II shows some abnormal appearances which are classed under theta activity. This sobriquet was originally given to rhythms found in cases of subcortical tumour but the term has since been adopted quite legitimately to include, also, rhythms in the same frequency band which are associated with functional, rather than organic, disorders. It is interesting that the identity of this type of rhythm was not recognized until the advent of automatic analysis; until then it was usually referred to as a "slow alpha rhythm" but its significance is quite different from that of the various aberrations of alpha activity, to be described later. Records containing theta activity are much harder to interpret than those with the classical delta rhythm and there is only very rarely a truly focal theta discharge. Perhaps the most trustworthy pathological sign is a persistent inalterable rhythm in the theta band and this is more satisfactory when it is unilateral. It is almost impossible to be certain of pathology when theta rhythm is encountered in children below the ages of 10-12, if only a single record is taken. Here again, persistence is an important diagnostic feature, since the theta components of children's records are characteristically labile, both in terms of

Another type of technical refinement is the automatic analysis of the records in terms of their various components, in the form of a frequency spectrum. This device is now fairly familiar. Its function is merely to assist the interpreter by disclosing components invisible to the naked eye and to provide quantitative information, where previously only qualitative descriptions were available. Automatic frequency analysis can be combined with topography in such a way that the local activity of quite small cell groups can be detected and measured, and the anatomical dissemination or suppression of the various modes of activity can be quite accurately traced. This type of study is of particular value in organic conditions, as compared with, for example, cases of epilepsy, since there is less danger of overlooking transient or paroxysmal changes, which are still best studied by means of the conventional multi-channel recorder.

One of the most healthy signs in electro-encephalography is the tendency to include on the record a registration of other variables beside the E.E.G. itself, and thus, respiration, electrocardiogram, blood-pressure, skin resistance, muscular activity and so forth appear more and more frequently in electro-encephalographic tracings, so that the correlation of nervous and somatic perturbations can be more readily made.

The limitation imposed on ordinary electro-encephalography by having to record through the unopened skull is still serious. There is still no trustworthy method of distinguishing between cortical and basal activity, but the use of special electrode designs and placements has produced some promising results. The bipolar nasal or pharyngeal electrode provides at least a different approach to the basal structures, though these still remain relatively inaccessible to the electro-physiologist. When direct access can be obtained to the brain through a burr-hole or during an operation, both the cortex and the deeper structures can be explored with no more damage than is caused by the ordinary brain needle, which can be converted into a satisfactory bipolar electrode of small dimensions. Naturally, opportunities for such observations occur only in cases where organic disease is suspected, so that information on entirely normal human brains has not been obtained in this way, but in many cases the abnormal region occupies only part of the operative field so that direct comparisons of healthy and disturbed function can be made at all cerebral levels. Apart from the physiological interest of such data, the precise delimitation of subcortical new growth and abscess formations has been found of considerable practical value. This procedure, at least, requires only the simplest recording equipment and can be combined with the withdrawal of specimens for biopsy.

One may anticipate that valuable observations may be made in the future by combining the technique of direct exploration with the experimental procedures to be discussed later.

We may now turn to the enumeration of those features of the electro-encephalogram which are suggestive of organic pathology. It may be best to consider them, at first, quite empirically, in order to outline the scale of variation. First of all there are the classical slow rhythms which were originally called "delta" waves. A summary of the facts relating to these is contained in Table I. It will be seen that great care is necessary in interpreting records containing only this type of abnormal activity, particularly when the diagnosis lies between an organic condition and one of, for example, idiopathic epilepsy. The data summarized under the heading "Wave-form" are of the greatest importance, since it is the irregularity and variability of the discharges which seem to suggest an acquired lesion. It is tempting to suppose that this irregularity is due to the presence of many independent components, as suggested by the frequency analysis, for this would fit in well with the conception that the lesion

engage the activity of several fundamental physiological mechanisms, yet is a most ominous sign. It is most common in young people and is always associated with a history of some sort of seizure, though there is not always evidence that the patient is having an attack while this discharge is in progress. It has recently been observed that discharges of this type can often be evoked or driven by physiological stimuli, when these are presented at a frequency near to that of the spontaneous discharge rate. Occasionally even non-rhythmic stimulation can precipitate or accentuate this discharge.

This leads on to the sixth class of abnormal features, the anomalies which can be observed in the electrical responses evoked by various types of stimuli. Photoc stimulation is the most convenient and effective form of stimulus, if for no other reason because the areas concerned with vision and visual association are so large and accessible in man. In normal subjects the type, degree and extent of the response are very variable both from person to person and from moment to moment. Here again, the degree of symmetry is an important factor, though, even in this respect, certain normal persons present a startling picture. Of course when there is widespread destruction of the visual areas no response can be evoked from that region, but rather harder to understand is the tendency of areas adjacent to damaged or dys-

ABNORMAL E.E.G. FEATURES SUGGESTIVE OF ORGANIC PATHOLOGY

TABLE II.

THETA (4 to 7 c/s).

Amplitude: Greater than 20 μ V in adults but resembles psychopathy.

Frequency: Typically 5 to 6 c/s.

Wave-form: Simple.

Persistence: Persistent when deep structures directly involved. When paroxysmal or responsive (to physical or emotional stimuli) resembles psychopathy and juveniles.

Topography: When focal suggests underlying deep lesion. When diffuse wide involvement of deeper structures (trauma, tumour).

GENERAL SIGNIFICANCE

Involvement of cortico-thalamo-hypothalamic circuits and structures near third ventricle.

TABLE III.

ALPHA (8 to 13 c/s).

Asymmetry

(a) *Amplitude:* Greater than 50% between hemispheres.

(b) *Topography:* Extension beyond parieto-occipital region. Restriction to less than 50% area on normal side.

Asynchrony

(a) *Frequency:* Consistently more than 0.5 c/s between hemispheres.

(b) *Fluctuation:* Frequent unilateral bursts.

Persistence: Total persistence (resembles certain psychotic conditions).

Asymmetrical Responsiveness: To either mental or physical stimuli beyond known normal limits.

TABLE IV.

SPIKES

Usually focal, sometimes bilateral.

GENERAL SIGNIFICANCE

Cortical irritation; usually associated with seizures. Frequently result of trauma, particularly birth trauma.

SLOW SPIKE AND WAVE (*not* wave and spike of *petit mal*)

Often focal but sometimes bilateral. Most common in children.

GENERAL SIGNIFICANCE

Profound pathology of varied and unknown types, associated with minor, akinetic and myoclonic seizures.

EVOKED ACTIVITY (Photoc Stimulation)

Absence of response at fundamental stimulation frequency. Disproportionately large response at harmonic frequencies above 18 c/s.

trophic projection fields to exhibit activity only at frequencies harmonically related to that of the stimulus rate. It would appear as though in such cases the response to

minutes and months. This is an opportune stage to emphasize the enormous importance of repeated recordings in cases of suspected organic disease. The French workers have devoted much attention to what they call the anatomo-clinical evolution of the E.E.G. and all workers would agree that the changes in the picture from day to day or week to week are of great importance, both in distinguishing organic from functional and epileptic disorders and in helping to establish a differential diagnosis as between static, recovering and progressive lesions. While considering the question of theta rhythms it should be emphasized that these components are not simply a milder form of delta activity; they do not occur merely as a result of slight cortical damage but are definitely correlated with a subcortical disturbance and particularly with perturbation of the relations between the cortex and basal structures. Moreover, the occurrence of rhythms in this frequency band in normal people, in certain transitory, emotional states suggests that they may have a function analogous to that of the better-known alpha rhythm in subserving the mechanism of sensorimotor integration.

The relation between the amplitude and extent of delta and theta activity, both topographically and temporally, can be used to infer the extent and rapidity of evolution or decline of a pathological process. For example, cases in which the first abnormal feature is a diffuse but lateralized theta discharge followed after a matter of weeks or months by a more focal delta rhythm on the same side have been found post mortem to have tumours arising near the third ventricle and growing outwards. An inverse relationship in order of time suggests a lesion arising superficially, invading the deeper structures. There are, however, many anomalies and paradoxes in such cases and, as always, these often provide evidence of important fundamental truths.

Table III indicates, briefly, some of the disturbances in the normal alpha rhythms which can be taken as abnormal signs. Clearly, when an area of the brain, normally associated with alpha activity, is destroyed, the rhythm is absent from that region and the same is, of course, true of the smaller, less rhythmic components of the E.E.G. There are, however, cases more complex than this; the interpretation of such records depends largely upon comparison of the two hemispheres, since the normal variations of symmetry are very much less than those of alpha activity as a whole. There are normal people who show no alpha activity whatever and those in whom the rhythm can be blocked only by the reading aloud of an interesting sentence. Rather as in the case of the theta rhythm, abnormalities in the alpha category are more often signs of interference with physiological circuits and anatomical pathways than of cortical involvement, and for this reason such cases should be studied by experimental methods in order to work out the site and nature of the interference. Here again also, automatic analysis is a great help not only in separating the various components but also in identifying their focus and extent, a very difficult task when several rhythms of similar frequency are spatially adjacent or overlapping.

Table IV contains several other abnormal features. The brief discharges generally called "spikes" are as truly abnormal as the focal delta discharge but have, of course, an entirely different significance. They are almost certainly signs of irritation rather than depression and are usually very localized when they occur in relation to trauma. As the Montreal School has demonstrated, they often arise a little distance away from the apparently traumatized area and indicate a target for intervention even better than do the obvious signs of damage.

A very peculiar and still poorly understood feature in certain records is the slow spike-and-wave complex which, in some ways, resembles but is actually quite distinct from the classical wave-and-spike discharge associated with minor seizures. This is actually one of the most intriguing of all cerebral abnormalities since it appears to

syphilis or disseminated sclerosis, and to Dr. D. L. Davies for a group of 14 cases of Friedreich's ataxia which he has studied and which I have included here.

Table I shows the diagnostic groupings studied. It is seen that the E.E.G. is abnormal in 45% of the total group, but tends to be more abnormal in the inflammatory than in the degenerative cases and particularly severely in the G.P.I.s, the presenile cortical atrophies and in Huntington's chorea. It is rarely abnormal in disseminated sclerosis. Of the cases with severely abnormal E.E.G.s (16 in number), 4 are acute cases of G.P.I. and 4 cases of presenile atrophy with gross mental confusion or fits. There is a case of Friedreich's ataxia with episodes of automatic behaviour considered epileptic, a case of Wilson's disease, 2 recent severe vascular accidents and the remaining 4 cases showed mental confusion.

TABLE I.—E.E.G. IN ORGANIC CEREBRAL DISEASE
(Excluding Neoplasm and Trauma)

	No. of cases	E.E.G. abnormal	E.E.G. severely abnormal
<i>Inflammatory (46)</i>			
G.P.I.	16	9	4
Other neurosyphilis	14	1	0
Post-encephalitic	16	13	0
<i>Degenerative (89)</i>			
Presenile cortical atrophy	16	8	4
Friedreich's ataxia	14	3	1
Huntington's chorea	6	5	5(?)
Cerebro-cerebellar degeneration	12	4	1
Vascular accidents	12	5	2
Cerebral arteriosclerosis	5	2	1
Prolonged cerebral anoxia	4	3	1
Disseminated sclerosis	13	2	0
Chronic drug intoxications	5	4	1
Malignant hypertension	2	2	1
<i>Others (9)</i>			
P.M.A. Sturge-Weber's syndrome, compulsive tic, arteriovenous aneurysm, sup. long. sinus syndrome, congenital alexia, essential hypertension	9	4	0
Total	144	65	16 (? 21)

Note: If the five patients with Huntington's chorea and absence of rhythmical activity are included there are 21 severely abnormal E.E.G.s (see text).

TABLE II.—SYMPTOM GROUPS

	No. of cases	E.E.G. correlation	E.E.G. severely abnormal
Aphasia	10	—	—
Retinal blindness	5	—	—
Chronic hemiplegia	14	—	—
Cerebellar ataxia	21	—	—
Parkinsonism	8	—	—
Parkinsonism + behaviour disorder	8	+	—
Choreo-athetosis	6	—	—
Gross mental confusion	5	+++	+
Intellectual deterioration	29	+	—
Fits	16	+	—

I have attempted a further analysis from 122 relevant cases between the *main symptom groups* (Table II), the involvement of *special systems* within the C.N.S. and the E.E.G. findings. Finally, the abnormal E.E.G. patterns themselves have been examined and four types have emerged with considerable frequency (Table III). These

the stimulus was arriving by an indirect route at the secondary areas and filtered by some intervening mechanism, so as to contain only the higher components of the primary response. There is a peculiar biochemical relationship in some of these cases; a lowered blood sugar enhances the effect, which may be almost negligible after a heavy meal or when glucose has been drunk. This, again, suggests that elementary physiological mechanisms are revealed and of these, so far, we know almost nothing.

Consideration of this summary of facts and notions leads one to the conclusion that future progress in applied electrophysiology will depend more and more upon intimate knowledge of the functional anatomy of the nervous system and rather less upon technical contrivances. The line of approach taken by Dusser de Barenne and continued so ably by his pupils and collaborators has brought many of the bewildering diagrams in the anatomical textbooks to life and discoveries in this field are reported almost daily. There is no doubt that within a few years it will be possible to rely upon a complete functional anatomy of the central nervous system and this very great victory will be reflected in the value and scope of electro-encephalography.

Side by side with this advance goes the study of the subtle and elusive mechanisms of central nervous action. It is peculiar that we have dallied so long with the electrical phenomena represented in the electro-encephalogram, without insisting upon their identifying themselves in relation to function. The modern concept that the spontaneous rhythms seen in the brain may have a specific and essential part to play in transforming sensory data into material for conscious perception helps considerably to explain some of the aberrations and anomalies listed above.

It is, perhaps, inevitable that, being a physiologist, I should seem to consider the desperate human problems presented by organic cerebral disorder more as preparations than as patients. It is one of the great pleasures of this work that at all times this cool and detached attitude can be moulded and orientated by the enthusiastic collaboration of the physicians and surgeons who have humanitarian, as well as scientific, duties.

Dr. Denis Hill: The value of electro-encephalography as a clinical test for the location of space-occupying lesions of the cortex and subcortical centres is now generally recognized. There is an extensive literature and recent reviews have compared the technique favourably with other clinical methods and with the use of air-replacement. The position regarding trauma of the brain is similar, although it has received less attention. A few reports have appeared of the E.E.G. findings in acute and chronic encephalitis and in neurosyphilis, but none, as yet from this country. In the case of expanding lesions and cerebral trauma, the extent of the damage to nerve tissue is usually widespread, is not confined to any specific pathways or systems and the effects upon the E.E.G. are often the result of widespread destruction, cerebral œdema or raised pressure in the ventricles. It is only rarely in the case of the expanding lesion that the changes in the E.E.G. can be related to impairment of function within known functional pathways. Consideration of the chronic degenerative processes in which the sites of pathological lesions are known might provide evidence of the relation between such lesions and particular changes in the E.E.G. My remarks will, therefore, be concerned with the findings in 144 cases of organic disease of the nervous system, a group collected from the material at the National and Maudsley Hospitals, to exclude expanding lesions. The group includes 46 inflammatory cases and 89 cases classed as degenerative. Since patients with such conditions are not usually referred for E.E.G. examination, the number is not large considering that it represents the total collected over a period of four years. I am indebted to Dr. Worster-Drought who referred from the West End Hospital 25 patients with neuro-

FIG. 1.—Treatment of patient with G.P.I. by penicillin. 25.1.46. (before treatment started): High voltage generalized 3-4 c/sec. delta rhythm, maximal in frontal areas; patient disoriented with gross mental confusion. 28.1.46: Marked reduction in delta rhythm; emergence of occipital "slowed alpha" rhythm at 6-8 c/sec., and frontal fast rhythm. 4.2.46: Further improvement; no delta rhythm. 28.3.46: Normal occipital alpha rhythm at 9-10 c/sec. Generalized fast rhythm. Sensorium clear but failure of memory for recent events.

four types have been related to the presumed sites of action of the lesion present. The clinical data on which this has been done was necessarily not always complete.

INVOLVEMENT OF SPECIAL SYSTEMS

Degeneration in the large afferent and efferent systems in the spinal cord, seen in the cases of Friedreich's ataxia and tabes dorsalis, did not influence the E.E.G. Cases of cerebellar agenesis and degeneration were also normal. 2 cases of oculomotor nuclei degeneration were normal. 5 cases of choreo-athetosis were normal but a case of Wilson's disease was severely abnormal. Marked changes were found in 5 out of 6 cases of Huntington's chorea, but none in post-encephalitic Parkinsonism, without severe personality changes. In view of the known importance of thalamic nuclei for the production of cortical rhythms it is unfortunate that no patient has been examined in whom the predominant lesion could be ascribed to the thalamus. Turning to the predominantly cortical lesions, whether the E.E.G. is abnormal would appear to depend on the acuteness and severity of the lesion. Unilateral vascular lesions, embolic or thrombotic, leave the E.E.G. abnormal on the side for a few days or weeks, but later the rhythms tend to return to normal. In presenile atrophy also, during the acute phases of the condition, the E.E.G. is very frequently abnormal and often focal, but later may become normal again. The case of G.P.I. is very similar and 5 treated patients within this series had normal E.E.G.s. (Fig. 1) In a number, however, this was not the case and it would seem that the appearance of a new pattern of E.E.G. rhythm supervening after an acute inflammatory or degenerative process tends to conform to a type and to be associated with diffuse cortical destruction and with some degree of intellectual deterioration.

TYPES OF E.E.G. ABNORMALITY

The types of E.E.G. abnormality found can be classified under four headings:

- (1) Generalized delta rhythm (less than 4 c/sec.) which is rhythmical and symmetrical in the frontal areas. Local delta rhythm, which is usually irregular, containing poly-rhythmic components.
- (2) Theta rhythm excess (4-7 c/sec.) bilateral, parieto-temporal and symmetrical.
- (3) "Slowed" atypical alpha rhythm 6-8 c/sec. occupying the post-central areas, showing poor blocking response to visual attention.
- (4) Absence of rhythmical activity, in all areas or in a local area, at rest, on eye closure and during overbreathing.

TABLE III

Type	Clinical groups	Symptom correlates
(1) (a) Generalized delta (<4 c/sec.)	(a) Acute G.P.I. Acute vascular accidents Drug or hypertensive encephalopathy	Mental confusion
(b) Local delta	(b) Acute vascular accidents Acute G.P.I. Acute cortical atrophy (presenile)	Fits
(2) Theta rhythm excess (4-7 c/sec.)	General: Especially post-encephalitic	Behaviour disorder Personality change
(3) "Slowed alpha" (6-8 c/sec.)	Chronic diffuse cortical inflammatory and degenerative processes	Dementia
(4) Absence of rhythmical activity		
(a) General	(a) Huntington's chorea	
(b) Local	(b) Severe local atrophic lesions in chronic stage	

by mechanical and chemical stimulation of local cortical areas, particularly in the frontal regions, but this mechanism is purely cortical and does not involve subcortical "suppressor" circuits.

In the light of these physiological observations it is of interest that cortical rhythms are unaffected by the lesions of choreo-athetosis but suppressed by those of Hunting-

FIG. 3.—Two cases of Huntington's chorea. Absence of rhythmical activity with the eyes shut. No change during or after voluntary overbreathing.

ton's chorea. It seems improbable that deterioration within the thalamic nuclei could have been sufficient to account for the absence of rhythmical activity in 5 out of 6 cases, nor is it likely that the posterior hypothalamic nuclei were destroyed in these cases. It is probable that the association of an atrophic process in the frontal cortex and in the basal ganglia is the significant factor since neither alone produces either persistent depression or facilitation of cortical rhythm.

To summarize, the normal rhythmical activity of the postcentral cortex, called the alpha rhythm, is dependent upon intact cortical neurones, especially the deeper layers, and upon thalamo-cortical connexions. From the present series of cases, nothing can be learnt about the effects of lesions within the thalamus. When large areas of cortex are *destroyed*, the areas involved may show little rhythmical activity, a state similar to a local "suppression" described by Dr. Denis Williams (1945). When the cells of large areas of cortex are involved in *dysfunction* from toxic, inflammatory or degenerative processes, local very slow or delta wave activity occurs. Whether the E.E.G. in the area returns to normal or shows absence of activity later would appear to depend upon the degree of recovery and the extent of the final cellular destruction. If epileptic activity supervenes in the cortex near-by an area of destruction, a persistent E.E.G. abnormality may remain of epileptic type. Interference with thalamo-cortical projections on one side results in diminished rhythmical activity on that side.

10 cases of "slowed" alpha rhythm occurred. These were 5 cases of presenile dementia, one post-encephalitic state, 3 patients with diffuse vascular disease (fig. 2, one case illustrated) and one patient with Gilles de la Tourette syndrome.

FIG. 2.—Cerebral vascular disease; aphasia. "Slowed alpha" rhythm at $7\frac{1}{2}$ c/sec. Slight reduction in the amplitude of activity in the anterior parts of the lead on the left side.

DISCUSSION

I believe that this is the first report of the E.E.G. findings in Huntington's chorea, choreo-athetosis, Friedreich's ataxia and other cerebellar degenerations. Recently interest for electro-encephalographers has shifted from the cerebral cortex to the thalamus and basal ganglia, clinically because of Dr. Grey Walter's finding of theta rhythm excess in cases of tumours around the third ventricle, and physiologically because of the effects on cortical rhythms of ablation and stimulation of subcortical grey matter, reported by Kennard and Nims (1942), Morison and Dempsey (1943), Murphy and Gellhorn (1945), Obrador and others (1943). The finding of a "suppression" or absence of cortical rhythm in cases of Huntington's chorea (fig. 3), in which both basal ganglia and cortex suffer degeneration, must be contrasted with cases of choreo-athetosis and Parkinsonism in which the E.E.G. is normal and with cases of post-encephalitic Parkinsonism with severe personality and mental changes in which an excess of theta rhythm is found.

Experimental work on animals has shown that both these effects—the facilitation of slow activity and the "suppression" or abolition of all cortical activity—can be produced by interference with subcortical grey matter. Thus, stimulation of the striatum by Gerebtzoff (1941) produced abolition of cortical rhythms, while destruction produced an excess of theta rhythm. Murphy and Gellhorn found that electrical stimulation of the posterior nuclei of the hypothalamus produced fast rhythms in the cortex while Obrador (1943) found that destruction in this area resulted in abolition of the normal potentials.

The common path for both these effects on the cortex must be through thalamic nuclei:—In the case of the striatum via globus pallidus and possibly lateral ventral thalamus, in the case of the hypothalamus via mammillothalamic tract and dorso-medial nucleus. In the case of the hypothalamic-thalamic system it has been shown that the areas of the cortex which will fire the hypothalamus lie in the prefrontal, sensorimotor and cingulate gyri. It has also been shown (Leao and Morison 1945) that spreading depression of cortical activity over both hemispheres can be induced

by mechanical and chemical stimulation of local cortical areas, particularly in the frontal regions, but this mechanism is purely cortical and does not involve subcortical "suppressor" circuits.

In the light of these physiological observations it is of interest that cortical rhythms are unaffected by the lesions of choreo-athetosis but suppressed by those of Hunting-

Fig. 3.—Two cases of Huntington's chorea. Absence of rhythmical activity with the eyes shut. No change during or after voluntary overbreathing.

ton's chorea. It seems improbable that deterioration within the thalamic nuclei could have been sufficient to account for the absence of rhythmical activity in 5 out of 6 cases, nor is it likely that the posterior hypothalamic nuclei were destroyed in these cases. It is probable that the association of an atrophic process in the frontal cortex and in the basal ganglia is the significant factor since neither alone produces either persistent depression or facilitation of cortical rhythm.

To summarize, the normal rhythmical activity of the postcentral cortex, called the alpha rhythm, is dependent upon intact cortical neurones, especially the deeper layers, and upon thalamo-cortical connexions. From the present series of cases, nothing can be learnt about the effects of lesions within the thalamus. When large areas of cortex are *destroyed*, the areas involved may show little rhythmical activity, a state similar to a local "suppression" described by Dr. Denis Williams (1945). When the cells of large areas of cortex are involved in *dysfunction* from toxic, inflammatory or degenerative processes, local very slow or delta wave activity occurs. Whether the E.E.G. in the area returns to normal or shows absence of activity later would appear to depend upon the degree of recovery and the extent of the final cellular destruction. If epileptic activity supervenes in the cortex near-by an area of destruction, a persistent E.E.G. abnormality may remain of epileptic type. Interference with thalamo-cortical projections on one side results in diminished rhythmical activity on that side.

The E.E.G. can also be altered by lesions in some fibre systems terminating in the thalamus, but is unaffected in cerebellar lesions, mid-brain lesions or lesions of the long sensory tracts. Lesions confined to the extrapyramidal system do not alter the pattern, which is normal in choreo-athetosis and Parkinsonism. How the depression of cortical activity in Huntington's chorea is mediated remains an interesting problem.

Dr. Denis Williams: *The clinical use of the electro-encephalogram.*—Many papers have been written about the use of the electro-encephalogram (E.E.G.) in the localization of cerebral lesions, and there has generally been a reasonable correlation between the predicted and actual site of the lesion. In any study of these contributions there is a natural tendency to link the E.E.G. changes to the causal lesion, and to forget that the electrical abnormalities which are seen arise, in fact, from the brain which is damaged by the lesion.

Dr. Grey Walter has given us an outline of the recent advances in electro-encephalographic technique and of their applications to the interpretation of the different wave-forms seen in the abnormal E.E.G. He has also related some of the groups of abnormal rhythms to the groups of clinical disorders which are mainly responsible for them. Dr. Denis Hill has analysed the contributing causes of abnormalities in the E.E.G. in some of the conditions which are associated with an impairment of consciousness. I would like to consider briefly the part the E.E.G. has to play in contributing to knowledge about the nature of lesions in the cerebral hemispheres, quite apart from its admitted value in localizing them.

No single clinical method can be used, alone, to establish a complete understanding of the kind of lesion which might be present in any organ, but the clinician finds it necessary to integrate all the evidence he can accumulate to hazard a reasonable prediction of the characteristics of an unseen lesion which is causing a demonstrable disorder. Similarly the E.E.G. cannot often be used, alone, to establish a diagnosis. It must be related to all other clinical, pathological, and radiological data which have been placed at his disposal.

What further information can the E.E.G. give about the nature of a lesion of the hemispheres, apart from its approximate site? It seems that it may give evidence upon six of its qualities.

(1) *Extent.*—The E.E.G. merely records the electrical activity of damaged brain tissue, but the area of this can be mapped out within the limitations of a technique which includes recording through the thickness of the scalp and cranium. Disordered brain may for instance be found in the other hemisphere, or even in the unexpected hemisphere. The sharpness of definition of the abnormality may also be judged.

(2) *Severity.*—The degree of damage which is taking place at the time of recording may be judged by the period, voltage and persistence of the abnormal waves. Complete destruction may go unobserved, or may be recognized in abolition of the normal rhythms.

(3) *Absolute destruction* may be recognized by a "silent area" in which there is absence or reduction of electrical activity, but its certain recognition must often wait upon relating the E.E.G. and the radiological changes.

(4) *The depth* of the lesion in the hemispheres may be surmised, at least to a consideration of whether it lies in the cortex, the white matter, or the basal ganglia, by relating clinical observations to the voltage and period of the abnormal waves, and to the extent of their diffusion over the scalp. For instance, low voltage 3-a-second waves, obtained over a wide area in one hemisphere, particularly if associated with 7-a-second waves in one or both hemispheres, suggest a deep lesion.

(5) *Secondary changes*.—Long-standing lesions give rise to characteristic changes in the E.E.G. which have many features by which they can be distinguished from the immediate and direct effects of brain damage on the E.E.G. These secondary changes often precede, or are associated with, epilepsy.

(6) *Associated changes*.—Physical disorders which may be associated with cerebral lesions give widespread changes in the E.E.G. which are often symmetrical, and fairly easily recognized. Such changes are seen with high intracranial pressure, changes in consciousness, or in toxic states. For their correct interpretation knowledge of the clinical story is essential.

It is clear that in each of these six instances the E.E.G. can only be interpreted reasonably if the interpreter has full knowledge of other aspects of the clinical problem. That this is essential is made evident by the fact that there is usually more than one—and there may be many—possible explanations for any isolated phenomenon which may occur in the E.E.G. Even a sequence of related phenomena in the E.E.G. may be unsusceptible of interpretation if considered alone. For example:

(1) With a suspected lesion of the hemisphere, absence of abnormal slow waves in the E.E.G. may be due to absence of any lesion or to complete destruction of the damaged brain. For example, a large meningioma or a large porencephalic cyst may be associated with normal E.E.G. records.

(2) Suppression of normal rhythms in both hemispheres may be due to widespread destruction of parenchyma, to recent and benign concussion, or to personal idiosyncrasy.

(3) Episodes of abnormally fast waves may recur in widely dissimilar conditions, such as epilepsy, syncope, intoxications with drugs, such as medinal, or again as a personal idiosyncrasy of a normal subject.

(4) Episodes of slow waves are seen in epilepsy, in states of impaired consciousness, in normal sleep, and also in association with psychopathy.

There are even circumstances in which it is quite impossible to recognize which is the abnormal hemisphere, when unilateral changes are seen in the E.E.G., unless clinical data are available. When, however, the clinical findings are related to the E.E.G., further information is immediately available upon the nature of the lesion. For instance, abnormal rhythms recorded from the right side of the scalp in a patient with a right hemiplegia and aphasia suggest that the absence of abnormality from the left and presumably abnormal hemisphere is due to suppression of activity here. This suppression, with no abnormal slow waves, indicates that at the time of recording the left-sided lesion is causing no active brain destruction. Such a state of affairs is found with benign tumours, or after vascular catastrophes. The clinical story will probably distinguish between these two conditions. Such a record would eliminate, for instance, a malignant glioma, a secondary carcinoma, or a recent abscess.

Even when the E.E.G. is found to be perfectly normal, a clinical story may be essential for a correct interpretation. Conditions in which this may be so are as follows:

(1) When several symptoms and signs persist after a head injury. If the E.E.G. has returned to normal no further organic resolution can occur, and the prognosis for functional recovery is correspondingly bad. This is so whether the disorder is the result of brain destruction or of associated neurotic illness. So long as abnormality is still present in the E.E.G. and resolution is still occurring a final bad prognosis need not necessarily be made.

(2) When a normal E.E.G. is found in an epileptic the story must be known, for it may be a chance finding in a severe constitutional epileptic or it may be used to support the tentative diagnosis of cysticercosis, since the E.E.G. is normal as often in this condition as in the normal population.

(3) When organic dementia is taking place as a result of a slowly progressive condition such as cerebral arteriosclerosis or Alzheimer's disease, the E.E.G. is usually normal. Here again, therefore, when the clinical story is known the normal E.E.G. should be used to approach a correct diagnosis and a reasonable prognosis.

(4) If a normal E.E.G. is found in a patient who on other grounds is thought to have an expanding lesion of the hemispheres, the differential diagnosis is much reduced, since the more malignant and actively infiltrating tumours are improbable, and a recent abscess impossible.

From the argument which has been advanced in this short paper it seems that the E.E.G. should not be used alone to localize a cerebral lesion. It should rather be interpreted with the help of all the other evidence, which may have been quite sufficient to localize the lesion, to add to the knowledge of the site, extent, and severity of brain damage occurring at the time, and also to reveal the other associated, and perhaps unexpected, changes which may be taking place.

Records and case abstracts were then given to show the way in which the E.E.G. has been used recently to elucidate changes, and clinical changes to elucidate obscure E.E.G. findings.

Surgery in the Treatment of Rheumatoid Arthritis and Ankylosing Spondylitis

By W. ALEXANDER LAW, O.B.E., M.D., F.R.C.S.

ABSTRACT.—The pain, deformities and disabilities resulting from rheumatoid arthritis and ankylosing spondylitis must be treated by a team composed of physician, physical medicine expert, orthopaedic surgeon, and, in certain cases, deep X-ray therapist working simultaneously.

The principle of "rest" in order to relieve pain has to be combined with methods designed to preserve and restore function. The multiple joint deformities in these cases may necessitate a long programme of reconstructive or functional treatment, which entails whole-hearted co-operation on the part of the patient in intensive post-operative exercise regime.

Procedures advocated for the upper limb include excision of the acromion process together with the subacromial bursa to allow free movement between the central tendon of the deltoid and the tendinous shoulder cuff: arthrodesis of the shoulder in cases where there is more severe joint destruction; in certain cases of elbow-joint arthritis, excision of the radial head and sub-total synovectomy may preserve joint function and avoid or delay the necessity for arthroplasty which can be carried out in two ways: (a) similar to the formal joint excision, or (b) re-shaping the lower end of the humerus and upper end of the ulna lining these surfaces with fascia. The former method is preferable in cases of rheumatoid arthritis. To overcome wrist-joint deformity and restore pronation and supination excision of the lower end of the ulna together with radiocarpal fusion in position for optimum function is advocated. Finger and toe joints may be corrected by resection of the bone ends and capsulectomy.

In the lower limbs bilateral involvement of the hip-joint is best treated by vitallium mould arthroplasty which may be carried out in four ways: (1) Routine arthroplasty; (2) Modified Whitman procedure; (3) Modified Colonna operation; and (4) The proximal shaft or intertrochanteric arthroplasty. It is essential in these operations to have knowledge of the operative technique, the use of special hip gouges and reamers, and detailed post-operative supervision.

For dorsal kyphosis of the spine, spinal osteotomy at the lumbar level provides excellent correction but is an operation demanding care and skill in its execution.

The author's remarks are based on experience gained when working with Dr. M. N. Smith-Petersen at the Massachusetts General Hospital, Boston, U.S.A.

RÉSUMÉ.—Le traitement de la douleur, des déformités et de l'infirmité qui résultent de l'arthrite rhumatoïdale et de la spondylite ankylosante nécessite le travail simultané d'une équipe composée du médecin, de l'expert en médecine physique, du chirurgien orthopédiste et, dans certains cas, du thérapeute pour la radiothérapie profonde.

Le principe du "repos" pour le soulagement de la douleur doit être combiné avec les méthodes destinées à préserver ou à rendre la fonction.

Les déformités articulaires multiples dans ces cas peuvent rendre nécessaire un long programme de traitement reconstructif ou fonctionnel, demandant la coopération absolue du malade dans un régime d'exercices postopératoires intensifs.

Les procédés recommandés pour le membre supérieur comprennent l'excision du procès acromial avec la bourse sous-acromiale, pour permettre le mouvement libre entre le tendon central du muscle deltoïde et la manchette tendineuse de l'épaule; l'arthrodesis de l'épaule en cas de destruction plus sérieuse de l'articulation; l'excision de la tête du radius et la synovectomie sub-totale dans certains cas d'arthrite du coude pour permettre d'éviter ou de remettre à plus tard l'arthroplastie, qui peut être exécutée par deux méthodes (a) semblable à l'excision classique de l'articulation ou (b) la réformation de l'extrémité inférieure de l'humérus et de l'extrémité supérieure du cubitus, recouvrant ces surfaces avec de l'aponévrose. Dans le rhumatisme articulaire la première de ces méthodes est la meilleure. L'excision de l'extrémité inférieure du cubitus avec fusion radio-carpe dans la position permettant la meilleure fonction possible est préconisée pour combattre la déformité du poignet et rendre la pronation et la supination. Les articulations des doigts et des orteils peuvent être corrigées par la résection des extrémités des os et la capsulectomie.

Pour l'extrémité inférieure le meilleur traitement de la maladie bilatérale de la hanche est l'arthroplastie avec un moule de vitallium, qui peut être exécutée par quatre méthodes: 1° l'arthroplastie de routine, 2° l'opération de Whitman modifiée, 3° l'opération de Colonna modifiée, 4° l'arthroplastie de la diaphyse supérieure ou arthroplastie intertrochanterique. Pour ces opérations l'essentiel est de connaître la technique, d'employer des gouges et des alésoirs spéciaux et de pratiquer des soins postopératoires minutieux.

Dans les kyphoses dorsales l'ostéotomie spinale lombaire corrige très bien la déformité, mais l'opération demande une exécution soignée et habile.

Les remarques de l'auteur sont basées sur l'expérience obtenue pendant son travail avec le Dr. Smith-Petersen au Massachusetts General Hospital, Boston, U.S.A.

КОНСПЕКТ.—Боль, искривления и немощность, которые являются следствием ревматического артрита и анкилозного спондилита, должны быть лечимы одновременно терапевтом, специалистом по физической медицине, ортопедическим хирургом и в некоторых случаях также и специалистом по глубоким Рентгеновским лучам.

Принцип полного отдыха для облегчения боли должен быть соединен с методами предназначенными для сохранения и восстановления функции.

Множественные суставные искривления в таких случаях вызывают необходимость длительного курса реконструкционного и функционального лечения, для которого необходимо полное содействие со стороны больного для интенсивного послеоперационного курса телесных упражнений.

Для верхней конечности предложены следующие операции: полное удаление акромиального выступа вместе с *bursa subacromialis* для дозволения свободного движения между центральным сухожилием дельтоида и сухожилистой лопаточной плеча, или же артродезис плеча в случаях серьезного повреждения сустава. В некоторых случаях артрита локтевого сустава, полное удаление головки radius и субтотальная синовектомия могут сохранить функцию сустава и даже устранить или временно отсрочить необходимость артропластики. Последняя может быть произведена двумя способами: 1) на подобие вышеописанного удаления сустава, или же 2) путем переобразования нижнего конца плечевой кости и верхнего конца локтевой кости и обшивания этих поверхностей фасцией. Первый способ предпочтается в случаях ревматического артрита. Для предупреждения искривления кистевого сустава и для восстановления пронации и супинации, рекомендуется полное удаление нижнего конца локтевой кости вместе со слипшимся лучевой костью с кистью в наилучшем положении для функции. Пальцевые суставы на руках и ногах могут быть исправлены резекцией концов костей и капсулектомией.

В нижних конечностях двухстороннее вовлечение бедренного сустава лучше всего лечить артропластикой при помощи витальной формы,—операция, которая может быть произведена четырьмя способами: 1) путем обыкновенной артропластики; 2) путем видоизмененной операции Витмана; 3) путем видоизмененной операции Колонна; и 4) путем интертрокантерной артропластики. Эти операции требуют, во-первых, знания оперативной техники и, во-вторых, употребления специальных бедренных инструментов для выдалбливания и рассверливания, а также тщательного послеоперационного надзора.

Для дорсального кифоза спины, спинная остеотомия на уровне поясницы дает прекрасное исправление, но эта операция должна быть произведена осторожно и искусно.

Автор основывает свои заметки на опыте, приобретенном в Массачусетской клинике доктора Смит-Петерсон, в Бостоне, Соединенные Штаты.

EXTRACTO.—El dolor, las deformidades ó la imposibilidad física a consecuencia de artritis reumatoidea ó espondilitis anquilosante, deben ser tratados por un equipo compuesto de un internista, un experto en fisioterapia, un cirujano ortopedista y, en ciertos casos, por un radiólogo, todos trabajando simultaneamente.

El "reposo" como medida fundamental para aliviar el dolor, ha de combinarse con métodos destinados a conservar ó restaurar la función.

Cuando las múltiples deformidades articulares exigen un largo tratamiento reconstructivo ó funcional, el éxito está vinculado a la sincera colaboración del paciente durante el régimen de ejercicios postoperatorios.

Los procedimientos recomendados para el miembro superior, comprenden: resección del acromion y de la bolsa subacromial, para proporcionar amplia movilidad entre el tendón proximal del deltoides y el ligamento capsular del hombro; artrodesis del hombro cuando la destrucción articular es más severa; en ciertos casos de artritis de codo, la resección de la cabeza radial, con sinovectomía, puede preservar la función articular y evitar ó retrasar la necesidad de una artroplastia, la cual, si llega el caso, puede llevarse a cabo: (a) como en una resección articular corriente, ó (b) remoldeando el extremo inferior del húmero y el superior del cúbito y recubriendo las superficies con fascia. El primer método es el de elección en los casos de artritis reumatoidea. Para vencer las deformidades de la articulación de la muñeca y restaurar los movimientos de pronación y supinación, se recomienda la resección del extremo inferior del cúbito y soldadura radio-carpal en posición de óptima función. Las articulaciones de los dedos de las manos y de los pies, pueden ser corregidas por resección de los extremos óseos y capsulectomía.

La artroplastia con casquete de vitalium es el mejor tratamiento a emplear cuando la articulación de la cadera está afectada bilateralmente. Pueden seguirse cuatro técnicas: (1) Artroplastia corriente; (2) Procedimiento de Whitman modificado; (3) Operación de Colonna modificada ó (4) Artroplastia

intertrocantérea. Es esencial en éstas operaciones conocer bien la técnica, usar gubias de cadera y escarizadores especiales y prestar cuidadosa vigilancia postoperatoria.

Para cifosis de la espina dorsal, la osteotomía a nivel de las vértebras lumbares proporciona una corrección excelente, pero es una operación que exige ser ejecutada con gran cuidado y habilidad.

Las observaciones de los autores son fruto de la experiencia obtenida trabajando con el Dr. M. N. Smith-Petersen en el Massachusetts General Hospital, Boston, Estados Unidos.

In recent years the orthopædic surgeon has been taking a greater share in attempting to overcome the pain, deformities and disabilities resulting from rheumatoid arthritis and ankylosing spondylitis.

A high standard of team-work is essential throughout the course of treatment, the team being composed of physician, physical medicine expert, orthopædic surgeon, and, in certain cases, deep X-ray therapist.

The commonly accepted treatment has been the avoidance of operations during the acute stage of rheumatoid arthritis, and the principle of rest is still the basis of all so-called "conservative" treatment. The aim of all treatment must be to relieve pain, to arrest the disease process and to preserve or restore function, and though rest treatment may help in relieving pain and arresting local disease, it may be harmful as regards restoration of function, particularly if, by putting one joint at rest, there is interference of function in the other joints of the limb.

The preservation of joint function is also hindered by muscle and bone atrophy, loss of ligamentous elasticity, and muscle spasm, which may be accompanied by fasciitis and bursitis, the result of friction between bone and muscle. It is essential to eradicate these secondary changes as a preliminary to any joint reconstruction, which itself should be considered before there are advanced destructive changes and before the bone is so atrophied and the surrounding soft tissues so fibrous that attempted movement between new joint surfaces merely results in further distortion.

Whilst the patient is undergoing surgical treatment a careful balance must be drawn, therefore, between rest and active exercises, pain being controlled, if necessary, by medication.

In many rheumatoid cases there are multiple joint deformities necessitating a long programme of reconstructive or functional treatment, and therefore requiring patient and persistent co-operation in the post-operative regime. The patient may also have to undergo one or more revisions of these operations in order to obtain a satisfactory end-result.

Prior to carrying out major reconstructive operations, it is important to remove foci of infection, to overcome anæmia, if necessary by blood transfusion, and to combat the tendency to infection in the poorly nourished tissues by an umbrella of penicillin.

As adjuncts to the operations such surgical measures as traction, plaster casts, with or without wedging or turnbuckle devices, braces, Gatch beds or plaster beds, are extensively employed and are of proved value.

Joint aspiration for effusion is particularly indicated in cases with a "joint-cycle", for instance pain in the knee one day, gross effusion the next, tendency to subside on the third day, followed by a quiescent period of eight or ten days.

My own personal series of cases treated along these lines is small, but during 1946 while working at the Massachusetts General Hospital, Boston, I had ample opportunity of studying many cases on the arthritic service of Dr. Walter Bauer and on the orthopædic service of Dr. M. N. Smith-Petersen.

Temporo-mandibular arthroplasty, by resection of the condyles of the mandible, enables patients to eat and talk more easily and is a very effective procedure, but recession of the mandible is likely to occur, with aspiration of the tongue during sleep, and in one case—following the operation on the second side—a tracheotomy was required.

It is possible to obtain a two-inch separation of the jaws with maintenance of molar apposition. This operation may be an essential preliminary to further procedures which require intubation for anæsthesia.

(1) *Upper limb procedures*.—A painful *shoulder-joint*, with adduction and internal rotation deformity at the gleno-humeral joint, is commonly seen in rheumatoid arthritis, and the accompanying muscle spasm is associated with a subacromial bursitis, which in time limits scapular movement, so that both components of shoulder movement are restricted.

Excision of the acromion process.—Acromionectomy—or acromioplasty as it is termed—together with removal of the villous subacromial bursa, eliminates the source of pain as well as allowing free movement between the central tendon of the deltoid and the tendinous shoulder cuff. Relief of pain also helps to relieve muscle spasm so that both gleno-humeral and scapulo-thoracic components of shoulder-joint function are improved.

The acromion process is osteotomized at the posterior margin of the acromio-clavicular joint, which may be left intact, though regrowth of the process appears to be less likely if the line of separation is taken through the joint itself. In closing the wound it is important

to suture the central tendon of the deltoid to the periosteal attachment of the trapezius muscle.

Where there is a more severe destruction of the shoulder-joint and the scapular muscles are adequate, arthrodesis of the gleno-humeral joint in a position of slight forward flexion, slight external rotation and about fifty degrees abduction provides good function. Care must be taken that excessive abduction is avoided, so that the arm can be adducted completely to the side, with rotation of the scapula.

(2) In rheumatoid arthritis of the elbow-joint spasm of the biceps muscle is a pronounced feature together with pain and restriction of movement, particularly pronation and extension. Smith-Petersen has drawn attention to the fact that the radial head may be drawn upward to impinge upon the capitellum so as to produce a joint defect. Excision of the head of the radius overcomes such faulty joint mechanics, and also enables a subtotal synovectomy to be performed with the result that pain is relieved, there is considerable improvement in the range of pronation, and a lesser increase in the range of flexion and extension.

The earlier this operation is performed, the better the functional result, and the greater the likelihood of avoiding complete joint ankylosis necessitating the more complicated arthroplasty procedure.

Formal arthroplasty of the elbow-joint with excision of the lower end of the humerus and upper ends of the radius and ulna is indicated when there is gross joint destruction or complete ankylosis. In traumatic cases a somewhat flail joint is likely to result, but in rheumatoid arthritis, owing to the loss of elasticity and fibrous contracture of the periarticular structures, a greater degree of stability is attainable, and therefore a more powerful limb.

This arthroplasty can also be performed by reshaping the lower end of the humerus and coronoid fossa of the ulna, excising the radial head and synovial membrane. The newly-shaped bone surfaces may be covered with fascia obtained from the fascia lata of the thigh or the triceps expansion. This method appears to provide greater stability, though there may be greater difficulty in obtaining more than the mid-range of mobility.

(3) The characteristic wrist-joint deformity is that of ulnar deviation with loss of dorsiflexion and rotation, which may be even further limited if there is also elbow-joint involvement. A useful procedure for restoring function of the wrist and hand is to excise the lower end of the ulna, and arthrodesis the radiocarpal joint in the position of maximal function—about twenty degrees of dorsiflexion. The whole procedure can easily be performed through an ulnar approach and markedly benefits pronation and supination as well as eliminating pain. In some cases, when deformity is minimal, it may be justifiable to excise the distal end of the ulna alone, thus enabling movement to be restored and eliminating pain in the inferior radio-ulnar joint.

The following is a brief outline of some of my cases:

I.—A. M., male, aged 37.

Eighteen years—psoriasis on elbows and knees. Treated also for trachoma. Fifteen months—painful swollen wrist-joints treated by gold injections. Nine months—involvement of feet, ankles, knees and elbows.

Pre-operative conditions.—Both wrists: Complete ankylosis in excessive dorsiflexion; pronation and supination limited to a few degrees only. Marked finger deformity.

Shoulders: Abduction 50 degrees. Complete loss of external rotation. 15 degrees internal rotation.

Operations.—June 1947: Excision of lower end of ulna and arthrodesis of left wrist. Excision of right acromion process. Excision of lower end of ulna and arthrodesis of right wrist.

July 1947: Excision of left acromion process.

November 1947: Sound fusion of right wrist and almost complete fusion of the left radiocarpal joint. Pronation, supination and rotation: Left 90 degrees; Right 120 degrees.

Shoulder movements	Left	Right	Shoulder movements	Left	Right
Abduction	90 degrees	160 degrees	External rotation ..	45 degrees	45 degrees
Forward flexion ..	160 degrees	160 degrees	Internal rotation ..	90 degrees	90 degrees

Improved function with less pain in elbows and fingers.

II.—R. H., male, aged 42.

1936: Onset of rheumatoid arthritis; widespread involvement. Ulnar deviation and flexion deformity of fingers. Wrist-joints ankylosed in slight flexion and radial deviation. Elbow-joint ankylosed at 60 degrees flexion on left and 160 degrees on right. Shoulder-joints, abduction on right to 45 degrees and to 35 degrees on left. Knees and hips, small range of movement only.

1947: Excision of right acromion process and lower end of right ulna. Arthroplasty of left elbow-joint. Right wrist: Pronation 45 degrees; supination 5 degrees. Right shoulder: Abduction 65 degrees—able to feed himself and place right hand behind the head. Left elbow: Range of movement 165 degrees to 85 degrees but following an accidental blow diminished to 155 degrees to 140 degrees with recurrence of pain and swelling.

Rheumatoid arthritis frequently attacks the metacarpophalangeal and interphalangeal joints primarily, or these joints may be involved secondarily to wrist, elbow or shoulder. In the latter case functional treatment directed towards the principal joint concerned may alleviate finger disability, but as a rule the combination of muscle spasm and gravity tends to produce characteristic disabling deformity of ulnar deviation, flexion and subluxation, and a stage may be reached relatively early when function can only be restored by operative surgery. Arthroplasty, consisting of resection of the bone ends and capsulectomy is useful for the metacarpophalangeal joints of thumb and fingers. Smith-Petersen has devised vitallium cups or moulds for these joints along the same lines as the hip mould, and has used them in a few cases, and some surgeons use fascia lata as an interposition substance; but whatever technique is employed it is essential to ensure correct post-operative rehabilitation and co-operation in the exercise regime on the part of the patient. As an alternative to arthroplasty, the metacarpophalangeal joint of the thumb may be arthrodeseis in a position of abduction and opposition. This procedure replaces a painful unsound ankylosis by a painless stable fusion against which the fingers can work to produce an adequate grasp.

(4) In the *lower limbs* the hip- and knee-joints frequently demand surgical treatment for pain and deformity associated with a variable degree of ankylosis, but measures to improve function are only indicated if the patient is willing to co-operate in a prolonged post-operative exercise regime. This is essential to restore muscle power and ligamentous elasticity, in addition to the contours of new joint surfaces, according to the principle of Wolff's Law, structure being adapted to function. Where the patient's morale is low and the muscles are markedly wasted and fibrotic, and particularly if there is unilateral involvement, stabilizing procedures such as arthrodesis may be indicated to relieve pain and enable weight-bearing in a sound mechanical manner. Unfortunately, in too many cases, the problem of bilateral painful stiff hips and/or knees has to be faced, and in these cases a strong plea is made for reconstructive operation before fibrosis of muscles and ligaments, and atrophy of bones, or joint degeneration have progressed too far. Even then, it is advisable to warn the patient that one operation may be insufficient to obtain the desired end-result, and that one or more revisions of the operation may be required to increase range of movement and enable the muscles to redevelop.

Smith-Petersen stresses this point forcibly with particular reference to vitallium mould arthroplasty of the hip-joint, and in a series of 25 cases reviewed personally, revision of the operation was required in 9 cases for loss of movement due either to bone proliferation, fibrous or bony ankylosis or faulty relationship of the mould, and 4 additional cases were revised for post-operative sepsis.

At revision, particularly if this is performed several years after the original arthroplasty, the effects of even limited function in the reformation of the joint are striking. The femoral head and the floor of the acetabulum are lined by smooth glistening cartilage, covered by thin synovial membrane, and the bone itself is sound and hard, in complete contrast to the soft, even putty-like bone, which is so frequently found at the first operation in these rheumatoid hip-joints. The vitallium mould retains its smooth gleaming surfaces throughout, being quite inert, and allowing the natural process of repair and reconversion to proceed unhindered in the hæmatoma around the femoral head and acetabulum, both of which have been re-fashioned at the level of raw bleeding bone.

Arthroplasty of the hip using fascia lata as an interposition substance was rarely very successful in rheumatoid arthritis, but the Smith-Petersen method with a vitallium mould, and the formation of a large deep acetabulum congruous with the femoral head, is of definite value.

In 1939 Dr. M. N. Smith-Petersen announced his technique of performing arthroplasty of the hip, his aim being to "create all the elements that make up a joint—joint surfaces, surface covering, and joint capsule". The inert mould enables organization of the surrounding blood-clot to form a joint capsule after congruous joint surfaces have been fashioned. Prior to vitallium in 1938, glass, viscaloid, pyrex, and bakelite had been used, experimental work extending as far back as 1923, and it was shown both by joint exploration and histological examination that the newly-formed joint surfaces consisted of fibro-cartilage, with areas resembling hyaline cartilage, covered by a true synovial membrane, which lined the new fibrous tissue capsule, and contained synovial fluid. Originally a two-stage procedure was the intention, but the inertness of vitallium has made the second stage of mould removal unnecessary, the mould becoming a "permanent insurmountable barrier to recurring ankylosis" (Smith-Petersen).

This clearly is an important advancement on such materials as Beer's membrane or pig's bladder, and fascia lata, with which there was a high incidence of recurring ankylosis, as well as further absorption of the femoral head and neck. Any hip-joint reconstruction must aim at producing a joint which is painless, stable, and capable of bearing weight. This form of

arthroplasty aims also at the restoration of a satisfactory range of movement, and thereby good function with return of muscle power.

The response to the procedure is in proportion to the degree of muscle wasting and other joint involvement, but even in the most severe bedridden cases it is usually possible to obtain enough hip-joint movement to allow of the sitting position and tripod locomotion with crutches. In addition the diminution of pain and muscle spasm, even though there may be contracture of the soft tissues, is of very real value to these patients.

In a few patients the increased use of the hip-joints results in knee-joint pain and effusion. This is temporary in nature and resolves with graduated exercises, as the circulation and muscle tone and power improve. Increased activity of the hip-joint following arthroplasty may also enable other joints to be spared the more severe effects of the disease process, owing to improved blood supply and muscle action.

In one case of rheumatoid arthritis involving the hip-joint a basal femoral neck fracture was sustained, and non-union resulted owing to the ankylosis of the femoral head in the acetabulum. Treatment by bone grafting of the fracture and performing mould arthroplasty resulted in union of the fracture and satisfactory hip-joint movement.

The accompanying table shows the range of movement attained in the series of reviewed cases and the value of the operation both to the patient and to the surgeon.

TABLE I.—RHEUMATOID ARTHRITIS OF HIP
Follow-up Study
Range of Movement and Estimation of the Value of the Operation

Years after operation		Average flexion range (degrees)	Condition of hip			
			Satisfactory (No. of cases)		Unsatisfactory (No. of cases)	
			To patient	To surgeon	To patient	To surgeon
0-2	..	44	20	17	3	6
2-3	..	47	2	1	—	1
3-4	..	62	5	5	—	—
4-5	..	43	2	1	—	1
Over 5	..	88	3	3	—	—

There are certain special technical points of importance in performing vitallium mould arthroplasty for rheumatoid arthritis of the hip-joint. It is advisable to make the new acetabulum larger and deeper, with a correspondingly large size of mould or cup which is freely movable in the new acetabulum and on the re-shaped femoral head. The greater part of the bone removal is from the acetabulum which is deepened to the inner pelvic cortex and made exactly congruous with the head by the use of special gouges and reamers devised by Smith-Petersen. The joint capsule and synovial membrane are excised completely, together with the rheumatoid pannus overlying the articular surfaces and margins of the femoral head and acetabulum, and any raw bone areas not covered by the vitallium mould are coagulated by diathermy in order to diminish the likelihood of new bone formation which would distort or re-ankylose the joint. Rheumatoid bone is soft and vascular so that blood loss may be severe during the gouging and reaming stage of the operation. This is counteracted by transfusion during the operation and as much as three pints may be necessary to maintain the hæmoglobin level. The atrophic nature of the bone and the desirability of obtaining a free range of movement may necessitate modification of the ordinary arthroplasty procedure. There are four types of reconstruction to consider:

(a) The routine arthroplasty in which the femoral head and the enlarged and deepened acetabulum are reshaped, made smooth and congruous, and a vitallium mould or cup is fitted in such a manner that movement is permitted both between the femoral head and the cup and between the cup and the acetabulum and yet a stable relationship is retained.

The complete excision of the joint capsule and synovial membrane, together with the rheumatoid pannus is also an important earlier step in the operation and may provide the explanation of the minimal pain suffered by these cases in both the early and later post-operative periods.

III.—A. C., male, aged 32.

1940: Onset of ankylosing spondylitis—pain and stiffness in spine. Plaster jacket and infra-red treatment.

1946: Progressive stiffness of both hips and pain. Deep X-ray therapy—no relief. Bilateral 30 degrees flexion deformity of both hips.

1947: May: Vitallium-mould arthroplasty of left hip. June: Vitallium-mould arthroplasty of right hip. December:

Hip-joint Movements	Right	Left	
Permanent flexion ..	20 degrees	10 degrees	Free from pain.
Flexion	45 degrees	50 degrees	Walking well with crutches—to transfer to walking sticks. Climbs stairs. Puts on own shoes and socks.
Abduction	20 degrees	20 degrees	
Adduction	10 degrees	10 degrees	He has a degree of dorsal kyphosis which at some future date may require treatment by spinal osteotomy.
Internal rotation ..	5 degrees	5 degrees	
External rotation ..	5 degrees	5 degrees	

IV.—S. R., male, aged 26.

1944: Treatment for "fibrositis" of back.

1944: Diagnosed as ankylosing spondylitis—no response to vaccine therapy.

1946: Complete ankylosis of dorsal and lumbar spine, and both hip-joints: knees partially involved. Doing clerical work in erect position.

1947: July 7: Vitallium-mould arthroplasty right hip. July 28: Vitallium-mould arthroplasty left hip. November: Walking with crutches—free from pain apart from aching in muscles undergoing re-development. Able to sit comfortably and perform straight leg raising.

Hip-joint Movements	Right	Left
Flexion	50 degrees	50 degrees
Abduction	10 degrees	10 degrees
Adduction	10 degrees	10 degrees
Arc of rotation (about neutral) ..	10 degrees	10 degrees

(b) *The modified Whitman* type of operation is indicated if the femoral head has undergone atrophy or the bone is so soft that in the course of reshaping it by gouging and more particularly by reaming, bone is lost to such an extent that the femoral neck is too short. The greater trochanter and its attached muscles are transposed down the femoral shaft either as a primary or secondary operation, thereby lengthening the neck over the proximal end of which the mould is applied.

(c) *The modified Colonna* operation has to be carried out if there has been a more severe degree of absorption or loss of the femoral head and neck. The muscles are detached from the greater trochanter which itself is gouged and reamed in conformity with the acetabulum and a suitable mould is fitted. Frequently it is essential to deepen the acetabulum by a vertical osteotomy of the roof margin in order to obtain a greater degree of stability between the mould over the greater trochanter and the acetabulum. The outer margin of the osteotomy is elevated laterally and the gap filled with iliac bone chips. This is a very effective method of obtaining a further half or three-quarters of an inch depth in the acetabular roof.

(d) Finally, if the greater trochanter is unsuitable for reshaping, the arthroplasty can be made at the level of the lesser trochanter—the proximal shaft or intertrochanteric arthroplasty. The reshaping is carried out as previously and if possible some degree of varus is obtained to encourage stability in the acetabulum, which itself can be deepened by the vertical osteotomy method.

These latter operations result in a loss of leg length, but this is of little significance in bilateral cases, and they do tend to produce more unstable joints than the simple arthroplasty procedure, but in cases of rheumatoid arthritis and ankylosing spondylitis owing to fibrosis in the periarticular structures and muscle spasm, the wider bone resection may be of definite value in preventing re-ankylosis, though this must be considered in conjunction with the likelihood of placing the various muscle groups at a mechanical disadvantage.

This latter type of reconstruction is somewhat similar to the Girdlestone and Stamm operations, though they are pseudarthroses and are more likely to remain unstable, in addition to requiring temporary or even permanent use of a walking caliper.

V.—W. S., male, aged 26.

Ten years' history of ankylosing spondylitis with complete fusion of both knees, hips, lumbar, dorsal, and cervical spine and restriction of shoulder movements.

October 1946: Excision of left femoral head and neck.

March 1947: Modified Colonna vitallium mould arthroplasty (right).

November 1947:

Hip-joint Movements	Right	Left
Flexion	35 degrees	45 degrees
Abduction	20 degrees	30 degrees
Adduction	10 degrees	15 degrees
Rotation	few degrees	20 mainly external

The left hip is still somewhat unstable and the limb is considerably shorter than the right.

arthroplasty aims also at the restoration of a satisfactory range of movement, and thereby good function with return of muscle power.

The response to the procedure is in proportion to the degree of muscle wasting and other joint involvement, but even in the most severe bedridden cases it is usually possible to obtain enough hip-joint movement to allow of the sitting position and tripod locomotion with crutches. In addition the diminution of pain and muscle spasm, even though there may be contracture of the soft tissues, is of very real value to these patients.

In a few patients the increased use of the hip-joints results in knee-joint pain and effusion. This is temporary in nature and resolves with graduated exercises, as the circulation and muscle tone and power improve. Increased activity of the hip-joint following arthroplasty may also enable other joints to be spared the more severe effects of the disease process, owing to improved blood supply and muscle action.

In one case of rheumatoid arthritis involving the hip-joint a basal femoral neck fracture was sustained, and non-union resulted owing to the ankylosis of the femoral head in the acetabulum. Treatment by bone grafting of the fracture and performing mould arthroplasty resulted in union of the fracture and satisfactory hip-joint movement.

The accompanying table shows the range of movement attained in the series of reviewed cases and the value of the operation both to the patient and to the surgeon.

TABLE I.—RHEUMATOID ARTHRITIS OF HIP
Follow-up Study
Range of Movement and Estimation of the Value of the Operation

Years after operation		Average flexion range (degrees)	Condition of hip			
			Satisfactory (No. of cases)		Unsatisfactory (No. of cases)	
			To patient	To surgeon	To patient	To surgeon
0-2	..	44	20	17	3	6
2-3	..	47	2	1	—	1
3-4	..	62	5	5	—	—
4-5	..	43	2	1	—	1
Over 5	..	88	3	3	—	—

There are certain special technical points of importance in performing vitallium mould arthroplasty for rheumatoid arthritis of the hip-joint. It is advisable to make the new acetabulum larger and deeper, with a correspondingly large size of mould or cup which is freely movable in the new acetabulum and on the re-shaped femoral head. The greater part of the bone removal is from the acetabulum which is deepened to the inner pelvic cortex and made exactly congruous with the head by the use of special gouges and reamers devised by Smith-Petersen. The joint capsule and synovial membrane are excised completely, together with the rheumatoid pannus overlying the articular surfaces and margins of the femoral head and acetabulum, and any raw bone areas not covered by the vitallium mould are coagulated by diathermy in order to diminish the likelihood of new bone formation which would distort or re-ankylose the joint. Rheumatoid bone is soft and vascular so that blood loss may be severe during the gouging and reaming stage of the operation. This is counteracted by transfusion during the operation and as much as three pints may be necessary to maintain the haemoglobin level. The atrophic nature of the bone and the desirability of obtaining a free range of movement may necessitate modification of the ordinary arthroplasty procedure. There are four types of reconstruction to consider:

(a) The routine arthroplasty in which the femoral head and the enlarged and deepened acetabulum are reshaped, made smooth and congruous, and a vitallium mould or cup is fitted in such a manner that movement is permitted both between the femoral head and the cup and between the cup and the acetabulum and yet a stable relationship is retained.

The complete excision of the joint capsule and synovial membrane, together with the rheumatoid pannus is also an important earlier step in the operation and may provide the explanation of the minimal pain suffered by these cases in both the early and later post-operative periods.

III.—A. C., male, aged 32.

1940: Onset of ankylosing spondylitis—pain and stiffness in spine. Plaster jacket and infra-red treatment.

1946: Progressive stiffness of both hips and pain. Deep X-ray therapy—no relief. Bilateral 30 degrees flexion deformity of both hips.

1947: May: Vitallium-mould arthroplasty of left hip. June: Vitallium-mould arthroplasty of right hip. December:

Hip-joint Movements	Right	Left	Free from pain.
Permanent flexion ..	20 degrees	10 degrees	Walking well with crutches—to transfer to walking sticks. Climbs stairs. Puts on own shoes and socks.
Flexion	45 degrees	50 degrees	
Abduction	20 degrees	20 degrees	
Adduction	10 degrees	10 degrees	He has a degree of dorsal kyphosis which at some future date may require treatment by spinal osteotomy.
Internal rotation ..	5 degrees	5 degrees	
External rotation ..	5 degrees	5 degrees	

IV.—S. R., male, aged 26.

1944: Treatment for "fibrositis" of back.

1944: Diagnosed as ankylosing spondylitis—no response to vaccine therapy.

1946: Complete ankylosis of dorsal and lumbar spine, and both hip-joints: knees partially involved. Doing clerical work in erect position.

1947: July 7: Vitallium-mould arthroplasty right hip. July 28: Vitallium-mould arthroplasty left hip. November: Walking with crutches—free from pain apart from aching in muscles undergoing re-development. Able to sit comfortably and perform straight leg raising.

Hip-joint Movements	Right	Left
Flexion	50 degrees	50 degrees
Abduction	10 degrees	10 degrees
Adduction	10 degrees	10 degrees
Arc of rotation (about neutral) ..	10 degrees	10 degrees

(b) *The modified Whitman* type of operation is indicated if the femoral head has undergone atrophy or the bone is so soft that in the course of reshaping it by gouging and more particularly by reaming, bone is lost to such an extent that the femoral neck is too short. The greater trochanter and its attached muscles are transposed down the femoral shaft either as a primary or secondary operation, thereby lengthening the neck over the proximal end of which the mould is applied.

(c) *The modified Colonna* operation has to be carried out if there has been a more severe degree of absorption or loss of the femoral head and neck. Hip-joint Movements	Right	Left
Flexion	50 degrees	50 degrees
Abduction	10 degrees	10 degrees
Adduction	10 degrees	10 degrees
Arc of rotation (about neutral) ..	10 degrees	10 degrees

(b) *The modified Whitman* type of operation is indicated if the femoral head has undergone atrophy or the bone is so soft that in the course of reshaping it by gouging and more particularly by reaming, bone is lost to such an extent that the femoral neck is too short. The greater trochanter and its attached muscles are transposed down the femoral shaft either as a primary or secondary operation, thereby lengthening the neck over the proximal end of which the mould is applied.

(c) *The modified Colonna* operation has to be carried out if there has been a more severe degree of absorption or loss of the femoral head and neck. The muscles are detached from the greater trochanter which itself is gouged and reamed in conformity with the acetabulum and a suitable mould is fitted. Frequently it is essential to deepen the acetabulum by a vertical osteotomy of the roof margin in order to obtain a greater degree of stability between the mould over the greater trochanter and the acetabulum. The outer margin of the osteotomy is elevated laterally and the gap filled with iliac bone chips. This is a very effective method of obtaining a further half or three-quarters of an inch depth in the acetabular roof.

(d) Finally, if the greater trochanter is unsuitable for reshaping, the arthroplasty can be made at the level of the lesser trochanter—the *proximal shaft or intertrochanteric arthroplasty*. The reshaping is carried out as previously and if possible some degree of varus is obtained to encourage stability in the acetabulum, which itself can be deepened by the vertical osteotomy method.

These latter operations result in a loss of leg length, but this is of little significance in bilateral cases, and they do tend to produce more unstable joints than the simple arthroplasty procedure, but in cases of rheumatoid arthritis and ankylosing spondylitis owing to fibrosis in the periarticular structures and muscle spasm, the wider bone resection may be of definite value in preventing re-ankylosis, though this must be considered in conjunction with the likelihood of placing the various muscle groups at a mechanical disadvantage.

This latter type of reconstruction is somewhat similar to the Girdlestone and Stamm operations, though they are pseudarthroses and are more likely to remain unstable, in addition to requiring temporary or even permanent use of a walking caliper.

V.—W. S., male, aged 26.

Ten years' history of ankylosing spondylitis with complete fusion of both knees, hips, lumbar, dorsal, and cervical spine and restriction of shoulder movements.

October 1946: Excision of left femoral head and neck.

March 1947: Modified Colonna vitallium mould arthroplasty (right).

November 1947:

Hip-joint Movements	Right	Left
Flexion	35 degrees	45 degrees
Abduction	20 degrees	30 degrees
Adduction	10 degrees	15 degrees
Rotation	few degrees	20 mainly external

The left hip is still somewhat unstable and the limb is considerably shorter than the right.

The post-operative regime for the four types of operation outlined is identical and is as follows:

The limb is suspended in a Hodgen splint and Pearson knee attachment with 5 lb. skin traction for four weeks. During this time attention is paid to rehabilitation of the musculature, and hip movement is also encouraged by the patient sitting up and lying down flat in alternate periods, for flexion and extension, together with knee flexion exercises. At the end of the fourth week, the traction is removed and roller-skate exercises are commenced for the abductor and adductor musculature. The skates are strapped on to the posterior aspect of the patient's ankles, and movement is carried out over a hinged platform, which can be inclined to increase resistance as the exercises progress. At the sixth week the patient is allowed up in a chair and progresses to exercise on a stationary bicycle, adjusting the seat for movement in flexion and extension. Walking is re-established best by using a walking machine prior to crutches and encouraging a goose-step type of gait initially. Crutches are maintained for three to six months, and during this time exercises are continued on a bicycle, by climbing stairs and by sideways and forwards jumping. Gait is improved and loss of Trendelenburg is achieved by paying considerable attention to the abductor muscles, and a walking-stick replaces the crutches as the patient's muscle power and stability improve.

Keeping a correct heel and toe movement with the hip pushed inwards towards the centre of gravity must be impressed upon the patient. Regular supervision is maintained for a period of at least two years, and the active co-operation of the patient in the regime is an important factor in obtaining a good functional result.

In cases where bilateral hip-joint reconstruction is indicated the ideal time to perform the second arthroplasty is two to three weeks after the first, thus quickly enabling both hip-joints to attain the same stage in the post-operative exercise regime, the rehabilitation programme being timed from the second arthroplasty. It is obvious that with two major operations following one another at such a short interval, great care must be taken in maintaining the patient's general condition, and in particular the blood picture. Prior to the second operation it is essential that the hæmoglobin level should be raised to as near 100% as possible.

Painful swollen *knee-joints* can always be rendered painless and stable by arthrodesis, but the retention of mobility is all the more desirable when adjacent hip- and ankle-joints are also involved in the disease. Formal arthroplasty of the knee, owing to the complex mechanics of the joint, has not yet reached as satisfactory a stage as in the hip, but in cases where the joint is grossly distended by synovial effusion, or the synovial membrane is thickened and villous, much can be achieved by excising the synovial membrane as completely as possible together with the semilunar cartilages. This procedure is particularly indicated in a joint undergoing periodic episodic derangement, with incomplete resolution between the attacks and consequent loss of extension. Meniscectomy (medial and lateral) allows increase in the joint space, the more so if hypertrophied fatty and synovial fringes are removed at the same time, and the partial synovectomy and posterior capsulotomy also aid in regaining extension. Internal derangement of the knee-joint, due to a meniscus lesion in a joint involved by rheumatoid arthritis, should certainly be treated by excision of the meniscus. When there is a severe and persistent flexion deformity with joint subluxation, posterior capsulotomy is only effective if combined with division of the posterior cruciate ligament, and even the lateral ligaments. Total synovectomy in these cases usually results in fusion of the knee-joint with loss of pain at the expense of movement.

In performing posterior capsulotomy difficulty may be experienced owing to dense adhesions and the proximity of the popliteal vessels. Subperiosteal stripping of the capsule off the posterior aspect of the femur may prove an easier and safer method, lengthening the hamstring tendons, if necessary, and draining for twenty-four hours owing to hæmatoma formation. Only gradual extension of the knee-joint should be done, in order to avoid over-stretching the tibial and peroneal nerves, which are kept under observation throughout.

Arthroplasty with removal and re-shaping of adjacent bone surfaces, which have been destroyed by the rheumatoid pannus, and the interposition of fascia lata or vitallium plates or moulds between the new bone ends, is only of value if the patient's morale and muscular system allow of intensive physical therapy in the post-operative period, as the stability, as well as the mobility, of the new joint is directly proportional to the muscle power of the quadriceps group in particular.

VI.—B. L., single girl aged 28. (Case of Dr. Smith-Petersen.)

At age of 9 years—involvement of hips, knees, shoulders and fingers.

Four distinct exacerbations with periods of relative quiescence only.

1941: November: Arthroplasty of left hip—vitallium mould. December: Arthroplasty of right hip—vitallium mould.

1942: October: Arthroplasty of left knee—vitallium mould. December: Arthroplasty of right knee—vitallium mould.

1944: Removal of mould from left knee.

1946: Removal of mould from right knee—all elements of a joint were present. November: 40 degrees flexion range in each hip. 20 degrees flexion range in left knee. 10 degrees flexion range in right knee.

Where pain and crepitus are prevalent in the femoro-patellar compartment of the knee in addition to X-ray evidence of destruction of the articular surfaces, excision of the patella together with any excessive villous synovial membrane is effective in reducing pain and maintaining function. It is important to make certain that the quadriceps apparatus is fully repaired, otherwise extensor lag and instability will interfere with knee-joint function. As a less radical alternative to complete excision of the patella, plastic operation on this bone, excising irregular or hypertrophic outgrowths and rendering it more congruous to the corresponding surface of the femur are of value, and it is possible that retention of a portion of the patella aids in repair and strengthening of the medial and lateral quadriceps expansions and consequently improves the quadriceps mechanism.

Pain, restriction in the range of movement and deformity of the *ankle-joint* are best treated by arthrodesis, fusion being obtained in about 10 degrees of equinus to allow for the heel on the footwear.

For pain and *fixed claw-toe* deformity of the *metatarsophalangeal joints*, excision of the metatarsal heads or bases of the proximal phalanges enables both the toes and metatarsus to be re-aligned and the metatarsal arch to be restored.

The operation is followed by a short period of immobilization in moulded plasters (two to three weeks), or toe correction may be maintained by intramedullary wires, and proceeds to a full active exercise regime. This is a useful method of treatment, but should be instituted before deformity is extreme and associated with secondary bursitis and fasciitis.

Adventitious bursæ should be excised together with abnormal bony excrescences, and neurectomy of the digital nerves should be performed if they have undergone neuritic changes or neuroma formation, thereby producing severe pain.

Spinal osteotomy is an operation devised by Smith-Petersen to enable the establishment of compensatory lumbar lordosis for severe kyphotic deformity of the dorsal spine. In one case both lumbar and dorsal osteotomies were performed, but Smith-Petersen is of the opinion that nothing was gained by the dorsal osteotomy. The patient believes to the contrary. This operation is performed in the lumbar region at levels showing a minimum of bony wedging, the excess bone formed in the interlaminar ligaments being excised together with wedges from the intra-articular facets in one or two stages at two or more levels. After detaching the ligamenta flava and passing a periosteal elevator anterior to the lamina and articular process, into the lateral intervertebral notch, the osteotomy is performed through the superior articular process of the vertebra above, in an oblique plane of 45 degrees with the frontal plane. The number of levels is determined by the extent of new bone formation in relation to the facets and intervertebral discs. Correction is then obtained by hyper-extending the spine so that the edge of the lamina above slides on a shelf of the lamina below, without compressing the cord or overstretching the soft tissues, particularly the femoral nerves and vessels. After satisfactory correction, spinal fusion is carried out by raising bone flaps from the laminae and using lamellæ from the spinous processes which were removed initially. The results of this operation are dramatic—one patient stating that he could see ahead for the first time in eighteen years—but it is a difficult operation, the spinal extension having to be carefully controlled. Post-operative distension and retention have to be anticipated being due possibly to stretching of the autonomic nerves. Later follow-up shows that these patients retain their improved position and are even able to discard their spinal support.

VII.—G. T., male, aged 37.

Twelve years—progressive pain and stiffness of spine with increasing flexion deformity. Recently pain in right hip, with flexion contracture. Severe dorsal kyphosis—when standing with knees straight the face is directed to the ground.

Blood sedimentation rate—39 mm. in one hour.

1947: July: Osteotomy of spine at lumbar 3 and 4 level. November: Spine soundly fused with compensatory lumbar lordosis. Now able to see 100 yards ahead. December: Able to see 20 yards ahead. Tendency to slump. For further correction, by spinal osteotomy at lumbar 2 and 3 level.

VIII.—G. M., female, aged 29.

Four years' history—ankylosing spondylitis treated by vaccine and deep X-ray therapy.

1947: July: Spinal osteotomy—excellent correction. August, September: Arthroplasty of left and right hips.

1948: January: Back soundly fused: wearing spinal support.

Hip movements:

Right hip: Flexion 50 degrees

Both hips: Abduction 15 degrees; Adduction

Left hip: Flexion 45 degrees

20 degrees; Arc of rotation 10 degrees.

No pain—walking erect with a good stride. Lumbar lordosis fully compensates dorsal kyphosis.

In conclusion I must stress that I have only summarized the place of reconstructive surgery in the treatment of the rheumatoid diseases, and have scarcely alluded to the various surgical measures employed for protective splintage, correction of deformity and arrest of the local arthritic process. In all phases of surgical treatment, however, it is essential to maintain a careful physiotherapeutic regime, with the emphasis on active exercise and muscle re-education, together with early movement of the newly reconstructed joint.

These major joint reconstructions are formidable operations, requiring courage and vision on the part of both patient and surgeon, but in many cases the benefit obtained is not only seen in the relief of pain, prevention of deformity and partial restoration of function, but in the marked improvement in the patient's morale and mental outlook, which is also an important factor in the treatment of rheumatoid diseases.

The President (Dr. Tegner) expressed his interest in the patient described by Mr. Law who injured an elbow-joint on which an arthroplasty had been performed and who developed a flare-up of the rheumatoid condition in this joint. Could joints on which arthroplasties had been performed undergo recrudescences of rheumatoid arthritis as bad as or worse than joints which had not been subjected to operation?

Mr. Law had spoken of ankylosing spondylitis as though it were the same disease as rheumatoid arthritis. This was the common opinion in America but in this country it was more generally believed that they were different diseases. Could Mr. Law throw any light on this in view of the fact that he had described rheumatoid bone as being soft and vascular? Was spondylitic bone of the same texture?

Dr. Guy Beauchamp asked for details of technique in the transposition of the greater trochanter in the reconstruction of the femoral head.

Mr. Law, in reply to Dr. Tegner, said that recrudescences could occur in joints which had undergone arthroplasty, and must be treated according to first principles. He was in agreement with the British view that rheumatoid arthritis and ankylosing spondylitis are separate diseases. In the latter there is a complete bony ankylosis, the bone being vascular and well formed, and not so soft or easily cut as in rheumatoid arthritis.

In reply to Dr. Beauchamp, Mr. Law stated that the trochanter with the attached muscles is detached by an osteotome, transposed downwards and fixed to the femoral shaft on its outer aspect by means of a vitallium screw or wire sutures. If the trochanter is used for articulating with the acetabulum it is re-shaped and made congruous with the acetabulum using the special gouges and reamers.

Section of Orthopædics

President—GEORGE PERKINS, M.C., F.R.C.S.

[November 4, 1947]

Death from Homologous Serum Jaundice following Nail-Arthrodesis of the Hip.
Specimen of Right Hip-Joint shown.—W. D. COLTART, F.R.C.S.

The Conservative Treatment of Lumbar Disc Lesions.—E. J. CRISP, M.B.

The majority of lumbar disc lesions, with or without sciatica, generally recover completely if treated by adequate conservative measures. Bed rest, by itself, is insufficient. In hospital, the bed-making routine subjects the patient to considerable movement, while if treated at home he gets up for toilet purposes.

The lumbar spasm which develops after a disc injury is protective, and holds the spine in the optimal position both for the patient's comfort and to allow healing to take place, and it is essential that movement at the site of the lesion should be minimal.

By the application of a plaster jacket the natural processes of repair may be not only assisted, but accelerated. The plaster is applied with the patient standing in the position of greatest comfort, and it is important that no attempt should be made to correct deformity. Anteriorly the plaster extends from the xiphisternum to the pubis, posteriorly from the inferior angles of the scapulæ to the tip of the coccyx. The plaster is accurately moulded to the pelvis and the lower ribs, and is cut away at the groins to allow the patient to sit down. The plaster is light, comfortable and allows him to remain ambulatory.

The patient rests in bed until the pain is relieved, usually a matter of a few days only, after which he is allowed to get up, and in due course to return to his usual occupation.

It is essential that the plaster, or replaster, should be worn for upwards of three months to ensure sound healing. The object of the treatment is not only to bring about repair of the injured disc, but also to produce a fibrous ankylosis of the affected segment, and thus prevent further trauma. Adaptive shortening of ligaments and muscles at the site of the lesion restricts movement to a minimum, especially forward flexion. After removal of the plaster hyperextension exercises are given, but lumbar flexion is left to return spontaneously. A lumbar brace is worn for a further three months as a safety measure, and to give the patient confidence.

Three cases of acute sciatica following rupture of an intervertebral disc were shown, wearing plaster jackets. All three patients, a blacksmith, a tailor's cutter and a clerk, derived such complete relief from this form of treatment that they were able to return to work within seven days of the application of the plaster.

Amputation of Toes.—J. S. BATCHELOR, F.R.C.S.

When first seen this patient was complaining of severe pain in the left foot, chiefly over toes and under metatarsal heads.

Examination showed that the second and fourth toes had previously been amputated. The remaining toes were stiff and clawed and there were tender callosities under all metatarsal heads. Amputation of the remaining toes has produced complete relief of symptoms; the patient has been able to resume his work as a farm labourer wearing an ordinary boot.

Acromioclavicular Dislocation.—J. S. BATCHELOR, F.R.C.S.

This patient sustained a dislocation of the right acromioclavicular joint when serving in the Army, and developed pain in the region of the joint particularly on abduction of the arm. Excision of the distal end of the clavicle relieved these symptoms but was followed by pain in the ulnar border of the forearm and hand, apparently

due to pressure of the lower trunks of the brachial plexus on the first rib, as a result of dropping of the shoulder girdle. These symptoms were completely relieved by use of a modified "Böhler's" clavicle splint which elevated the shoulder girdle.

Calvé's Disease of the Spine.—G. W. E. LITTLE, M.B. (by permission of ERIC LLOYD, F.R.C.S.).

A boy aged 4 years and 4 months who was brought to Out-patients' Department with the complaint that he was holding his head to one side and inclined to hunch his shoulders in a peculiar manner when looking upwards. This had been noticed for some few weeks, but had been getting worse.

Past history.—October 1945, pain in right hip. X-ray showed erosion right iliac bone (? tuberculosis), Plaster of Paris spica applied. March 1946, X-ray showed erosion left ilium similar to condition of opposite side, ? calcium deficiency. Given a course of calcium therapy. Shortly after this he developed a stiff neck. He had a heavy cold at the time with some pyrexia, but this cleared up while the stiffness of his neck continued. X-ray showed a defect of the fifth and sixth dorsal vertebræ. May 1946, admitted to hospital for treatment and was an in-patient for nearly a year.

Present state.—On examination, weight 35 lb., height 3 ft. A healthy-looking young boy. No abnormality was discovered beyond a mild degree of torticollis due to tightness of the right sternomastoid. His hip and spinal movements all appeared normal and he did not complain of any pain or tenderness.

X-ray showed an unusual deformity in the upper thoracic region and further pictures showed this to be probably due to Calvé's disease of the spine. There is marked collapse of the fifth dorsal vertebra associated with widening of the intervertebral disc space. There is no loss of intervertebral disc spaces. There is apparently expansion of the abnormal vertebral body laterally and tendency to such expansion with slight wedging of the sixth dorsal vertebra (figs. 1 and 2). X-ray of the skull, ilia and other long bones showed no abnormality.

FIG. 1.

FIG. 2.

Calvé's disease of the fifth thoracic vertebra.

His blood chemistry was normal: Serum calcium 10.9 mg. per 100 c.c. Alkaline plasma phosphatase 15.2 units. Inorganic blood phosphorus 3.8 mg. per 100 c.c. Mantoux 1/1000 negative on two occasions. E.S.R. 15 mm. in one hour.

Instability of the Longitudinal Arch.—A. G. APLEY, F.R.C.S.

History.—The patient is a first child born after a normal labour. At birth his head was small and he had a cyst on his back in the upper dorsal region. When he was 4 months old this cyst was removed. It is said to have been a dermoid. After this operation his head grew somewhat rapidly until it became larger than the average for his age. He sat up at 14 months and talked at 2 years. At the age of 2½ he was seen at an orthopædic hospital where he was diagnosed as hydrocephalus and bilateral pes calcaneo-valgus; the left foot was manipulated and put into plaster for a few months. Otherwise he had no treatment. The abnormally rapid growth of his head did not continue; in fact his mother says that from about the age of 3 it has scarcely grown at all.

He was first seen at St. Thomas's Hospital in August 1947 when he was aged 5, having never, up to that time, been able to walk.

Clinical findings.—The child has a large head, its circumference being 22 in. His facies are "adenoidal" in type and he seems rather backward (a condition which even his mother admits). His eyesight and hearing are normal, as also are the upper limbs, except for a small birthmark on the right arm. There is a scar in the mid-line overlying the upper dorsal spine where the cyst was removed. X-ray shows a bony defect in this area, but none elsewhere in the spine.

The feet: When the boy attempts to stand, both feet immediately collapse into marked valgus (fig. 1). The muscles, however, are all present and work; but they are not as strong as they should be at his age. The Babinski response is very definitely extensor on the right and probably extensor on the left.

Comment.—It seems more than likely that there is an underlying neurological condition to account for the lack of proper control of the feet. The rapid growth of the head following removal of the tumour from the upper dorsal spine suggests that this tumour might have contained a prolongation from the meninges.

Whatever the underlying neurological condition, the chief orthopædic interest lies in the feet. Why is it that although the muscles are under his voluntary control he is unable to stand normally? The suggestion is that he has never learnt how to stand; in other words he

FIG 1.

has failed to acquire a normal postural reflex so that, his muscles being unable to balance his body on his feet, his longitudinal arch collapses.

There is known to be some association between myelinization of the pyramidal tract and the acquisition of a flexor Babinski response. It is conceivable that such myelinization may, when it occurs, promote the development of the postural reflex.

Rotatory Frame for Plaster Beds.—E. T. BAILEY, F.R.C.S.

The frame consists of a wooden base of standard type with three cross bearers, which, instead of supporting the plaster shell direct, are grooved to take three circular discs. Each of these discs is divided into two halves, which are shaped to the respective anterior and posterior shells on their central aspect, leaving a complete circular periphery to rotate on the grooved frame. The nursing procedure to turn a patient consists of applying the anterior shell, followed by the three anterior halves of the

due to pressure of the lower trunks of the brachial plexus on the first rib, as a result of dropping of the shoulder girdle. These symptoms were completely relieved by use of a modified "Böhler's" clavicle splint which elevated the shoulder girdle.

Calvé's Disease of the Spine.—G. W. E. LITTLE, M.B. (by permission of ERIC LLOYD, F.R.C.S.).

Section of Ophthalmology

President—HAROLD LEVY, F.R.C.S.

[November 13, 1947]

Two Cases of Iridocyclitis.—M. SARWAR, M.B.

I.—Mrs. A. has been attending the Oxford Eye Hospital since October 1946, complaining of eyes being sore off and on for two months and gradually getting blurred. She was diagnosed as chronic iridocyclitis.

On examination.—R.E.: Vision 3/60 not improved. Slight ciliary injection. Many mutton fat K.P. at the back of the cornea. Cells floating in the anterior chamber. Multiple posterior synechia and destruction of pupillary margin. Organized exudate on the anterior lens capsule. No nodules on the iris. Fundus not seen.

L.E.: Vision 6/18 not improved. Slight ciliary flush. Pigmented K.P. in the centre of the cornea. One posterior synechia. Pigment on lens capsule. No nodules on iris.

Neck: Swelling of thyroid. Thyroid gland is enlarged.

Hands: The finger joints of both hands are swollen.

Kahn and W.R. negative in blood tests.

X-ray of chest revealed enlargement of hilar glands and appearances of sarcoidosis. Bony changes in the hands compatible with sarcoidosis.

II.—Mr. E. First seen at the Oxford Eye Hospital in June 1942. Diagnosed as chronic iridocyclitis.

On examination.—R.E.: P.L. only. Eye white. Many mutton fat K.P. at the back of cornea. Anterior synechia. No cells in the anterior chamber. New vessels on the iris and remains of nodules. Pupillary margin bound down. Organized exudate on the anterior surface of the lens. Tension high. L.E.: No P.L. Clinical findings similar to right eye.

Abdomen: Liver enlarged two fingerbreadths. Spots on the abdomen similar to De Morgan's spots.

Kahn and W.R. negative in blood tests.

X-rays of chest show enlargement of hilar glands and appearances of sarcoidosis.

Mr. Sarwar said that he showed these cases because of the infrequency of the condition and because in this case there were hilar changes and other features compatible with sarcoidosis.

(1) A chronic form of iridocyclitis associated with arthritis, nodules on tendons, &c., and signs of sarcoidosis was first described by Jonathan Hutchinson in 1873.

(2) Iridocyclitis associated with sarcoidosis may be of three types: (a) the type usually described, i.e. with nodules on the iris; (b) with no nodules on the iris; and (c) an ordinary type of iritis which clears up without causing much damage to the eye.

(3) Large doses of cod-liver oil appear to be of benefit in such cases.

MAY—OPHTHAL. I

discs, locking these with a double-studded bolt and then, with the aid of, usually, one assistant, turning the patient gently, through 180 degrees when the bolts are undone and the posterior shell removed. (See Fig. 1.)

FIG. 1.

The frames can be used for successive patients by reshaping the discs to new plaster shells as required, leaving the main part of the frame and the circular periphery of the discs as a constant entity for all cases.

The frames, as originally designed at the Orthopædic Centre, Northern Hospital, Winchmore Hill, are now obtainable at the Carpentry Department, British Legion Industries (Preston Hall) Incorporated, Maidstone, Kent.

Talipes Calcaneo-varus with Extreme External Rotation of Tibiæ.—P. G. EPPS, F.R.C.S.

FIG. 1.

P. K., female, aged 2 years 3 months. The talipes was treated by manipulation and plaster followed by modified Denis Browne splints and good correction obtained. She has just started walking and stands with feet pointing almost directly laterally. There was delayed development of the patellæ, which do not show on X-ray, and are now only just palpable clinically. The hips are normal.

The photograph (fig. 1), taken at 1 year and 6 months, shows the deformity well. She has no other congenital defects. The deformity

will probably need to be corrected by rotation osteotomy of the tibiæ.

(The report of this meeting will be concluded in the next issue of the *Proceedings* of the Section of Orthopædics.)

III. Trachoma Chronicum Cicatricum.

Female, aged 60.

Both eyes: Trachoma chronicum cicatricum.

Right eye: Serpiginous ulcer nineteen years ago. Healed by graft from the mucosa of the lip (London Jewish Hospital).

Biopsy result: The specimen consists of connective tissue and its covering of stratified squamous epithelium. The epithelium, 8 or 9 cells thick, shows: (1) Basal cells, which are cubical or low columnar, and whose oval nuclei stain moderately with hæmatoxylin and contain a few deeply staining chromatin particles. (2) Intermediate polyhedral cells between which are cell bridges. (3) Surface cells which are flattened but not keratinized. (4) Adventitious cells—an occasional polymorphonuclear leucocyte.

The outline of the deep surface of the epithelium is somewhat undulating, presumably representing the succession of imperfectly formed papillæ and interpapillary downgrowths.

In addition there are seen in the sections two epithelial downgrowths, a small solid one extending horizontally just below the epithelium, whereas the other, which has a hollow cavity, extends vertically to the surface for a distance equal to three or four times the thickness of the usual epithelial layer.

The subepithelial tissue consists of loose connective tissue, appearing somewhat œdematous in places, and well supplied with blood and lymphatic capillaries. Just below the epithelium it is infiltrated with lymphocytes and plasma cells in considerable numbers, together with some endothelioid cells. Situated also in this tissue are a few tubulo-racemose glands, whose acini are lined by columnar cells with nuclei near the cell base, whilst an outer cell layer is formed of darker small cubical cells. These glands resemble buccal glands.

In the specimen, the structure of the original mucous membrane graft is maintained both in its epithelial and subepithelial parts.

[December 12, 1947]

CLINICAL MEETING HELD AT THE MOORFIELDS, CENTRAL AND WESTMINSTER OPHTHALMIC HOSPITAL, MOORFIELDS, LONDON

Eight cases by E. F. KING, F.R.C.S.

I. Intra-ocular Copper Wire Foreign Body in the Cornea and Chalcosis Bulbi.

J. M., aged 25.

This man first attended hospital 28.11.47 with a recent and trivial laceration of the right eyebrow. At the same time it was noticed that he had a hook-shaped piece of copper wire embedded in the right cornea, one end of which was projecting into the anterior chamber. He had no knowledge of injury to the eye.

There was well-marked chalcosis oculi, a "sunflower" cataract and metallic iridescent lustre of the anterior lens surface and Descemet's membrane. Vision of this eye was 6/5, and of the left 6/6.

On 3.12.47 the piece of copper wire was easily removed with the aid of forceps through a superficial corneal incision. There was no loss of aqueous and healing of the corneal wound was uneventful.

The interest in this case is the patient's total ignorance of the presence of the foreign body, and also the well-established chalcosis of the anterior segment with retention of normal vision.

Mr. J. H. Doggart said that this was certainly a beautiful case of a kind which one did not usually get a chance of observing, simply because the eye was usually more disorganized. Mr. King had spoken of the endothelium, but it was Descemet's membrane which had the bluish colour showing in this case the characteristic of being far more marked at the limbus and gradually fading towards the axial portion of the cornea. At one time in this case the polychromatic lustre was so marked that it was quite easy to appreciate it with a loupes, but it was now not nearly so brilliant, and he was not sure whether the "petals of the sunflower" were not a little stunted. His impression was that the superficial lens opacity was less marked than it had been before this operation.

Mr. J. D. M. Cardell referred to a case in which a piece of copper wire had entered the eye with some considerable force, penetrating the cornea and the anterior capsule, but remaining within the lens, within which its total length was accommodated. No change occurred in the eye for eighteen months. At the end of that time a cataract rapidly made its appearance, and, fortunately, the copper wire came away with the lens material when the lens was evacuated with a curette.

Mr. J. P. F. Lloyd said that he had observed one very striking point in one of these cases. The multiple peripheral anterior synechiae in this case were an appearance that he had not previously observed. The mechanism of production would seem to be that the sheer bulk of the lesions in the iris brought them far enough forward to cause them to adhere to the posterior surface of the cornea.

Mr. R. Affleck Greeves said he would like to ask two questions, the first as to whether or not the ocular disturbance could remain limited to one eye only, and the second whether the ultimate prognosis was uniformly bad. He remembered seeing a young man with severe iridocyclitis in one eye, whose lungs were pronounced to show the typical X-ray appearance of sarcoidosis, and in whom the other eye remained unaffected. After a prolonged period the iridocyclitis cleared up under local treatment.

Dr. Noah Pines wondered whether the possibility of a tuberculous origin had been eliminated.

Mr. D. V. Giri said that a man aged 42 occupying an important position in Eastbourne was sent to him in 1940 for a second opinion. He was a high myope. Mr. Giri himself gave him no treatment, but the case went under the care of one of his London colleagues and was diagnosed as sarcoidosis. Such treatment as he received—X-rays to the chest, short-wave diathermy and atropine to the eyes, &c.—made his general condition worse without improving the condition of the eyes. After the cessation of all treatment, in the course of a year or more, the eyes quietened down of their own accord and his general condition improved remarkably. The left cornea had turned opaque and the eye was practically blind, but the right eye improved sufficiently to enable him to fulfil his important duties and he was very active physically too. This case demonstrates that sarcoidosis has a tendency to spontaneous recovery both locally and generally over a period of years.

POSTSCRIPT (Dr. Sarwar) 26.4.48.—The nodules in sarcoid of iris really appear more solid, and as Mr. Lloyd says, are solid enough even to cause an irregularity at the limbus when they are at the periphery of the iris. So far as is known, sarcoidosis is a self-limiting and self-resolving disease, and it is quite possible to get one eye involved—the other eye escaping. I am grateful to Mr. Greeves for pointing this out.

Tuberculin tests have been found negative in this condition and were so in these two cases. There is no relative lymphocytosis in the blood, and no general reaction; these points fairly exclude ordinary tuberculosis. Whether sarcoidosis is due to attenuated tuberculosis or not is not definitely settled yet.

The main danger of sarcoidosis in the iris is the pathological changes which it leaves behind. The disease process is cured sooner or later, but sequela-like posterior and anterior synechiae and persistence of big thick K.P. which may not absorb result in the functional destruction of the eye usually to a greater rather than a lesser extent. Mr. Giri's case must be counted as one of the fortunate ones where less interference has resulted.

Three Cases by NOAH PINES, M.B.

I. Trachoma Chronicum Cicatricum.

Mr. A. S., aged 54.

Both eyes: Trachoma chronicum cicatricum.

Right eye: Denig's operation twelve years ago (1935) (London Jewish Hospital). The middle part of the graft did not take. The end of the graft (at 3 o'clock) was removed and sent for investigations.

My thanks are due to Mr. Eugene Wolff, F.R.C.S., and to Mr. W. H. Gordon, Assistant Pathologist, Royal Westminster Ophthalmic Hospital, who kindly examined the specimen and reported as follows:

The epithelium throughout the section is stratified squamous, without cornification. It is not of uniform thickness, being much thicker over one-half of the section; the thicker half shows slight oedema of the prickle-cell layers (acanthosis). The papillae are stunted for the most part, though in the area of thin epithelium there are one or two considerable downgrowths of epithelium, which, however, remain quite regular in arrangement. The immediately subepithelial connective tissue is fairly close-fibred and in only one place (in the thick epithelium area) is there slight round-celled infiltration. The deeper connective tissue is looser and vascular.

The characters of the whole graft therefore are those of mucous membrane, slightly modified by stunting of the papillae, and, in part, by acanthosis.

II. Pannus Crassus ? Trachoma.

Mrs. A., aged 60, presented herself at Moorfields Hospital on 3.12.45 with a papilloma of the left upper lid. Biopsy revealed a granuloma. It later changed to a rodent ulcer and repeated biopsy revealed chronic conjunctivitis. Treated with penicillin without success. Now the upper lid is swollen, the tarsal plate thickened, the conjunctiva bulbi, as well as of the lids, are grossly inflamed. My thanks are due to Miss Ida Mann for supplying the previous history.

siderosis of this eye and pupillary dilatation was evident. The *left eye* showed well-marked siderosis of both anterior and posterior segments. There was a small sub-conjunctival foreign body on the nasal side about 9 mm. posterior to the limbus. Pupillary dilatation was limited in this eye, and the vitreous was too cloudy for any fundus details to be noted. The lens of each eye was found to contain congenital, grey and brownish dot- and club-shaped opacities throughout the cortex, chiefly distributed equatorally. The siderosis of the left eye had not noticeably altered the colour of these opacities in this eye, compared with the other eye, although there was anterior subcapsular rust-coloured deposit.

X-ray showed no radiopaque foreign bodies in the right eye, but a well-defined radiopaque foreign body in the left eye situated in the oral region in the 7 to 8 o'clock meridian.

At operation 7.11.47 a magnetic intra-ocular foreign body was removed from the vitreous through a posterior radial incision into the pars plana in this meridian. The ferrous metallic fragment was considerably decomposed, and, following it from the vitreous came three pieces of whitish plaster or concrete, similar to the pieces on the right iris.

The removal of these four distinct fragments from the vitreous is excellent evidence of the value of posterior route removal, as it would not have been possible by the anterior route, and, at the same time, proves that the foreign bodies in both eyes were the result of the explosion in 1940. It was not proposed to touch the foreign bodies in the right eye.

Examination in February 1948 showed that the left eye was already much improved. The patient states that he can now read the paper with the left eye, and vision is 6/36. The vitreous is much clearer. The pupil has already regained its full dilatation, which exposes previously unseen peripheral siderotic subcapsular spots in the lens. There was no retinal detachment, and no intra-ocular ill-effects could be observed from the operation. It is expected that the condition of this eye will improve still further. The rusty colour of the iris is already fading and now more nearly resembles that of the right eye.

The President said that he was aware of a similar type of case in which a man got a certain amount of concrete mixture in his eye. The anterior chamber was full of concrete particles, but the eye did not get very much inflamed, it quietened down, and he kept a fair amount of vision.

VIII. Macular Changes in Both Eyes in a Child Aged 7 Years.

Mr. A. J. B. Goldsmith said that the case reminded him very much of the description of toxoplasmal chorio-retinitis given by Colonel Derrick Vail in a Paper read before the Section in 1943 (Vail, D., *Proc. R. Soc. Med.*, 36, 629) and he wondered if the possibility had been considered. This condition typically gave rise to a bilateral macular choroiditis; it was, however, rare, very few cases having been described on the Continent of Europe, and not very many in America. The choroiditis in these cases was due to infection by toxoplasma, a protozoal parasite; the infection was thought to be transplacental from a mother who might herself show no stigmata of infection except perhaps a positive serological reaction. In the infant it was usually fatal, but occasionally the infection died out leaving as permanent evidence various forms of eye defect and, usually, calcified foci in the choroid of the ventricular system of the brain. He thought it would be worth while doing an X-ray of the skull and perhaps, serological tests.

Two Cases by A. G. CROSS, F.R.C.S.

I. Bilateral Aniridia, Glaucoma and Lens Opacities in a Woman.

Mr. A. J. B. Goldsmith asked whether the genetics in this case had been considered. The patient had told him she had two daughters who showed the same condition, although apparently her own parents were normal.

Mr. Cardell suggested that benefit might be obtained by tattooing the cornea in successive quadrants. He had had a case or two which had benefited. The tattooing might be so regulated as to be of a dark brown colour.

II. Band-keratitis in Man Aged 45.

Mr. J. Minton said that this might eventually become a compensation case. It would be very difficult for the ophthalmologist to decide whether it was an occupational disease or a corneal dystrophy. Anyone interested in medico-legal work would like guidance from the meeting. The man was working as a glassblower for thirty-one years without any trouble. Glassblowers do not show any corneal changes; they suffer from lens opacities.

Mr. A. J. B. Goldsmith said that he did not think there was any occupational basis in these cases. Some of his were doing well with weak atropine. In two cases he had scraped the cornea. It meant scraping off rather more than the epithelium, because this opacity was in and underneath

II and III. Retinal Glioma, with Successful Use of Radon Seeds.

In both children the eye with the more extensive growth has been removed and the other successfully treated by the application of radon seeds to the sclera over the growth.

II. Janet C., aged 12.

First attended hospital in November 1939, aged 3 years.

The right eye showed extensive glioma retinae, and was removed. Pathological section of this eye confirmed the nature of the tumour.

In the left eye there were two discrete masses of growth in the mid-periphery at 4.30 and 6 o'clock. Four radon seeds, each of 1.5 millicurie, were stitched to the sclera over the affected areas of the retina and left in situ for six days. Subsequent observation has shown satisfactory shrinkage of the growth and replacement by calcareous deposits. The visual acuity in this eye is now 6/24.

III. Diana P., aged 6.

First attended hospital in October 1942.

The right eye showed extensive glioma retinae and was removed. Pathological section of this eye confirmed the nature of the tumour.

In the left eye there were three discrete foci of growth, in the periphery at 3 and 6 o'clock and nasal to the disc at 10 o'clock. Six radon seeds, each of 1.5 millicurie, were stitched to the sclera over the affected areas of the retina and left in situ for five days. Periodic examination has shown satisfactory shrinkage of the growth. The vision of the eye is now 6/18, slight post-cortical irradiation cataract changes are present.

A younger sister of this child was brought to hospital in 1944 with a glioma in the right eye, which was removed. Fortunately no growth has so far appeared in the left eye.

In 1946 the mother of these two children attended hospital with a letter from her doctor to say that she was again pregnant and that he felt, in view of the history of glioma retinae in her two children, this pregnancy should be terminated. She was sent to a gynaecologist who in turn referred her to a psychiatrist. The psychiatrist agreed that the psychological strain on the mother was sufficient to justify termination of the pregnancy, which was carried out.

In reply to Mr. Seymour Philips, Mr. King said he had been guided by Sir Stanford Cade in regard to dosage of radon. The seeds had a stitch fixed to each end, which facilitated their attachment to the sclera.

IV and V. Two Cases of Myotonic Cataract.

The President said that during the war he had seen at a mental hospital a number of cases of myotonia dystrophica, but cataracts were not very frequent. He did not know whether they came late or appeared only in a certain proportion of cases.

VI. Syphilitic Uveitis.

VII. Foreign Bodies in Both Eyes (shown by H. H. SKEOCH, F.R.C.S.).

F. W., aged 33.

This man has been a diabetic under treatment for twenty years. He states that his eyes were injured in an air-raid in 1940 at Weybridge. Attended hospital on 5.9.47 complaining of, first blurring and later loss of vision in the left eye in the one day. Examination showed right vision to be 6/12, improved to 6/9 with myopic astigmatic correction. Left vision was less than 6/60 (H.M.). The right eye showed an extensive corneal scar (approx. 10 mm. long, obliquely across the upper part of the cornea). The healed corneal scar contained many fragments of debris, metallic and whitish pieces that looked like concrete or plaster. Scattered over the front of the iris and on the anterior lens capsule there were innumerable pieces of whitish material, similar to those in the cornea. Posterior synechia from 5 to 7 o'clock attached the pupillary margin to the anterior lens capsule, on which there was also some exudate. These multiple foreign bodies, both large and small, seemed to be causing no irritation or reaction in the iris tissues of this eye, but one or two large fragments in the angle of the anterior chamber at 6 o'clock were enclosed in endothelium. There was no

[January 8, 1948]

The Capsular Complications of Cataract Extraction

By CHARLES GOULDEN, O.B.E., F.R.C.S.

ABSTRACT.—The author considered the following important points:

- (1) Anterior capsular synechia to a corneal incision (made by a keratome) after the evacuation of a traumatic cataract. This might be detached early by the use of a blunt-ended knife following a perforation of the cornea with a sharp-pointed knife, much like a tenotome.
- (2) The involuntary prolapse of capsule with a cataract incision.
 - (a) The danger of this was demonstrated as the cause of glaucoma, especially if it be found necessary to divide opaque capsular membrane after the extraction.
 - (b) The danger of sympathetic ophthalmia.
- Prolapse might be prevented:
 - (a) By intracapsular extraction.
 - (b) By extracting the lens through an intact pupil, after the use of capsule forceps, followed either by a partial or total iridectomy.
- (3) The treatment of opaque after-cataract.

Various types of opaque capsule membrane were described.

 - (a) Opaque lens fibres imprisoned between anterior and posterior remains of capsule.
 - (b) Grey membrane made of new lens fibres from proliferating subcapsular cells.
 - (c) Elschnig's cells.
 - (d) Much thickened capsular membrane following an extensive hæmorrhage into the anterior chamber occurring about the fifth day after extraction.
 - (e) A thick membrane formed of fibrous tissue following the invasion of the coloboma of the iris after infection at the time of operation. The fibrous tissue comes from the undersurface of the conjunctival flap and causes an updrawn coloboma which is also made narrower by its contraction.

When performing a capsulotomy thickened bands should be avoided and an incision made in thin capsule, *parallel* to thick bands.

If the membrane is very thick and shows signs of being torn from its peripheral attachment when a single needle is used, then

- (1) Two needles may be used after the method of Bowman;
- (2) A Wheeler operation may be performed (Wheeler, 1939, *Collected Papers*, New York, 197);
- (3) Thick capsule may be divided by means of a Ziegler knife, as described by the author, but not in the manner described by Ziegler.

The danger of performing a capsulotomy in the presence of soft lens matter was pointed out.

The occasional occurrence of localized vitreous opacification at the site of a capsulotomy, even in the absence of iridocyclitis, was mentioned.

RÉSUMÉ.—L'auteur considère les complications importantes suivantes:

(1) Synéchie antérieure entre la capsule et l'incision cornéenne (faite avec un kératome après extraction d'une cataracte traumatique. On pourrait la détacher précocement à l'aide d'un couteau à pointe émoussée après perforation de la cornée par un couteau pointu semblable à un ténotome.

(2) Prolapsus accidentel de la capsule au moment d'une incision pour la cataracte.

(a) Le danger de cette complication comme cause de glaucome est démontré, surtout s'il se trouve nécessaire d'inciser une membrane capsulaire opaque après l'extraction.

(b) Le danger d'une ophtalmie sympathique.

Ce prolapsus pourrait être évité:

(a) Par l'extraction intracapsulaire.

(b) Par l'extraction du cristallin à travers la pupille intacte, après emploi de la pince à capsule, suivie d'une iridectomie partielle ou totale.

(3) Traitement de la cataracte secondaire.

Description de diverses formes de membrane capsulaire opaque:

(a) Fibres cristalliniennes coincées entre les restes antérieurs et postérieurs de la capsule.

(b) Membrane grise formée par de nouvelles fibres cristalliniennes provenant de cellules souscapsulaires proliférantes.

(c) Cellules d'Elschnig.

(d) Membrane capsulaire très épaissie suivant une grande hémorragie dans la chambre antérieure vers le cinquième jour après l'extraction.

(e) Membrane épaisse consistant de tissu fibreux, comme suite de l'invasion du colobome de l'iris après infection au cours de l'opération. Ce tissu fibreux vient de la surface inférieure du lambeau conjonctival et produit un colobome soulevé et rendu plus étroit par la contraction.

En faisant une capsulotomie il faut éviter les bandes épaissies et faire l'incision parallèle à ces bandes, dans une partie mince de la capsule.

Quand la membrane est très épaisse et semble être sur le point d'être arrachée de son point d'attache périphérique si on emploie une seule aiguille on peut:

(1) Se servir de deux aiguilles d'après la méthode de Bowman;

(2) Pratiquer l'opération de Wheeler (1939, *Collected Papers*, New York, 197);

(3) Sectionner la capsule par une méthode décrite par l'auteur, employant un couteau de Ziegler, mais pas de la même manière que Ziegler.

Bowman's membrane. Simple swabbing was useless; one had to peel off the superficial layers of cornea—they peeled off like the skin of an onion. Vision had been very much improved by this procedure. The operation was a partial superficial keratectomy.

The President said that if these corneæ were scraped they did fairly well; the condition did not tend to recur.

White Ring.—J. D. M. CARDELL, F.R.C.S.

First described by Coats in 1912, this is a condition which is probably more frequently present than described. The ring is small and, causing no symptoms, may be easily overlooked. The ætiology has been a matter of discussion for many years. Coats and Mayou considered it to be congenital, Ballantyne favoured intra-ocular disease, while others say it is due to superficial trauma.

The case shown probably falls into the last category. The man is an engine-driver, aged 63, who has had several "sparks" in the left eye. The picture differs in no way from the classical—a complete ring of dead-white, roughly circular, dots having a diameter of under 1 mm. at the level of Bowman's membrane.

Sarcoidosis of the Orbit, with Nodular Infiltration and Proptosis, Treated with Injections of

Chaulmoogra Oil.—HELEN DIMSDALE, M.D., M.R.C.P., for S. P. MEADOWS, M.D.

F. L., a man aged 52. In January 1946 he noticed puffiness of the eyelids. His general health was good. Past history of three attacks of left-sided pneumonia, the last attack twenty years ago.

On examination (February 1946).—Fundi, pupils, and external ocular movements normal. Hypertrophy, increased vascularity, and chemosis of the conjunctivæ, bilateral proptosis, left more than right, multiple hard nodular swellings in both lower lids. Enlargement of lacrimal, right parotid, pre-auricular, tonsillar and axillary glands. Liver and spleen not palpable.

Investigations.—Blood W.R. negative. Sedimentation rate 34 mm. in one hour. Blood-count: R.B.C. 5,400,000; Hb. 90%; W.B.C. 14,600 with normal differential. Plasma protein 7.3 gramme/100 c.c.; plasma albumin 3.8 gramme/100 c.c.; Mantoux 1/100 old tuberculin: very weak positive. X-rays: Hands and feet normal; chest—residual fibrosis. Biopsy of orbital nodule: Focal lymphocytic infiltration, epithelial histiocytes, and a multinuclear giant cell.

Progress.—He was treated with generalized U.V.L., but there was a gradual increase in size of the swellings, with tenseness of the orbital tissues, and severe conjunctival injection.

In July 1946 treatment with chaulmoogra oil was started. He was given 2 c.c. (3% solution) intramuscularly once a week for four months. The swellings softened and gradually receded.

In January 1947 he developed an acute left iritis which recovered in three months.

Present condition.—Well; has gained 2 stones in weight. Small nodule left lower lid; left lacrimal gland, and cervical lymph gland on the right side just palpable. Left eye old K.P.

REFERENCE

LOMHOLT, SVEN D. (1934) *Derm. Z.*, 70, 57.

Dr. Dimsdale, in reply to a question, said that chaulmoogra oil was used by Lomholt in 1934 for subcutaneous nodules. Recently the view had been taken that the improvement was spontaneous, as patients treated with tuberculin and other remedies had also recovered.

The following cases were also shown:

Two Cases of Keratitis.—G. FENWICK, F.R.C.S.Ed. (for HAROLD RIDLEY, F.R.C.S.).

Retinal Perivasculitis Treated with Penicillin.—H. E. HOBBS, F.R.C.S.

- г) Сильно утолщенная капсулярная оболочка, которая являлась следствием экстенсивного кровотечения в переднюю камеру и которая встречалась на пятый день после экстракции.
- д) Толстая оболочка из фиброзной ткани, которая являлась следствием вторжения колобомы радужной оболочки после инфекции во время операции. Фиброзная ткань происходит от нижней поверхности конъюнктивального локута и приводит вынутую вверх колобому, которая суживается от сокращения.

При капсулотомии нужно избегать утолщенные связки и разрез сделанный в капсуле должен быть параллельным к утолщенным связкам.

Когда оболочка очень толста и когда имеются признаки ее разрыва от периферального прикрепления при употреблении только одной иглы, можно—

- или 1) употреблять две иглы по способу Бомана;
- или же 2) произвести операцию Вилера (1939, сборник лекций, стр. 197);
- или же 3) перерезать толстую капсулю ножом Циглера по способу предложенному автором, а не Циглером.

Опасность произведения капсулотомии при присутствии мягкого хрусталика тоже описана.

Автор также отмечает, что изредка появляется местная непрозрачность стекловидного тела на месте капсулотомии, даже если и нет приодонциклита.

Capsular complications following cataract extraction have become rarer owing to improved technique in operating. They will become still rarer as time goes on and intracapsular extraction becomes better known and more widely practised; nevertheless, capsular complications will continue to arise. Many complications of cataract extraction are due to bad operating, but some capsular complications occur in the practice of the most skilful operators and follow an apparently perfect operation.

In this paper I refer almost exclusively to the operation in which the lens is removed from its capsule, an operation that leaves within the eye the greater part of the lens capsule.

Two types of incision are commonly used: one, in the cornea, and the other an incision at the limbus with the formation of a conjunctival flap, and there are certain advantages and disadvantages that attend each method.

If the incision is corneal, the retraction of the divided tissue is most marked at the anterior and posterior surfaces so that when the edges of the wound come together it is the central part, corresponding to the substantia propria, that meets, leaving a wedge-shaped gap anteriorly and posteriorly. The coagulum which is formed causes the edges of the wound to become adherent one to the other. The anterior wedge-shaped gap becomes filled with epithelium and the posterior gap with endothelium from the cells which line the membrane of Descemet. The cicatricial tissue that forms comes from the corneal corpuscles. As the scar develops it extends upwards into the anterior wedge-shaped area and gradually replaces the plug of epithelium that filled the anterior part of the wound, and in a similar way the posterior wedge-shaped area is filled by scar tissue and the endothelial plug replaced.

When the incision is through the limbus, with the formation of a conjunctival flap, there is a similar retraction of corneal-scleral tissue to that which occurs when the incision is corneal as described above, but in this case the anterior area is not filled with corneal epithelium, but by subconjunctival tissue derived from the deep surface of the conjunctival flap.

Corneal wounds have been found filled after twenty-four hours and experimental investigation of the healing of conjunctival wounds shows that the epithelium over the wound is complete in one hundred and twenty hours. Keratome incisions of the cornea are notorious for the rapidity and ease with which they heal; such incisions are very oblique and delicate, but an incision with a Graefe knife can be at right angles to the surface of the cornea and does not heal as rapidly, and as a result epithelium may line the wound and pass into the anterior chamber and indeed completely line it. A similar thing may occur if a closed corneal wound is reopened during the healing process. The result will be a secondary glaucoma and loss of the eye sooner or later. I have had an example of glaucoma that could not be relieved occurring within six weeks of the extraction.

If there is delayed agglutination of the wound at the limbus when a conjunctival flap has been formed then subconjunctival tissue extends between the two sides of the wound and it may produce a vascularized fibrous membrane which fills the coloboma and becomes continuous with the capsular remains. Again, when an intractable iridocyclitis has followed an extraction, there is frequently found imperfect closure posteriorly of the lips of the limbal incision due to an entanglement of the lens capsule. This is not merely due to the presence

L'auteur montre le danger d'une capsulotomie en présence de matière cristallinienne molle. Il parle de la formation, dans quelques cas, d'opacifications locales du vitreux à l'endroit d'une capsulotomie, même s'il n'y a pas d'iridocyclite.

EXTRACTO.—El autor considera los siguientes puntos importantes:

(1) Sinequia capsular anterior a una incisión corneal hecha con un querotomo, siguiendo a la evacuación de una catarata traumática. Puede ser despegada precozmente usando un cuchillo de punta roma, después de perforar la córnea con un bisturí afilado, de forma parecida a un tenotomo.

(2) Prolapso involuntario de la cápsula en la incisión operatoria.

(a) El peligro del prolapso está en que ha demostrado ser una de las causas de glaucoma, especialmente si ha sido necesario dividir la membrana capsular opaca después de la extracción.

(b) Peligro de una oftalmía simpática.

El prolapso puede prevenirse:

(a) Mediante extracción intracapsular.

(b) Realizando la extracción del cristalino a través de una pupila intacta, previa fijación de la cápsula con pinzas, seguido de iridectomía parcial o total.

(3) Tratamiento de la opacidad post-operatoria.

Se han descrito varios tipos de opacidad de la membrana capsular:

(a) Fibras opacas del cristalino aprisionadas entre los restos anteriores y posteriores de la cápsula.

(b) Membrana gris integrada por fibras cristalinas neoformadas por proliferación de células subcapsulares.

(c) Células de Elschnig.

(d) Engrosamiento de la membrana capsular a consecuencia de una extensa hemorragia en la cámara anterior, sobrevenida aproximadamente al quinto día de la extracción.

(e) Formación de una gruesa membrana de tejido fibroso siguiendo a la invasión de un coloboma del iris por infección durante la intervención. Este tejido fibroso procede de la cara interna del repliegue conjuntival y da lugar a un coloboma vertical, que se hace todavía mas estrecho al contraerse.

Al realizar una capsulotomía deben evitarse las zonas de engrosamiento, y la incisión, hecha sobre zona capsular no engrosada, deberá ser *paralela* a aquellas. Si la membrana es muy gruesa y muestra señales de despegarse de su inserción periférica cuando se usa una sola aguja, puede procederse como sigue:

(1) Pueden usarse dos agujas después del procedimiento de Bowman;

(2) Llevar a cabo la operación de Wheeler (1939, Collected Papers, New York, 197);

(3) Método descrito por el autor, el cual divide el engrosamiento capsular con el chuchillo de Ziegler, pero no con la técnica que describió Ziegler.

Se pone también de relieve el peligro que conlleva realizar una capsulotomía en casos de cristalino blando.

Se menciona asimismo la posibilidad de opacificación localizada del humor vítreo en el punto de la capsulotomía, contingencia que ocurre ocasionalmente, aun en ausencia de iridociclitis.

КАПСЮЛЯРНЫЕ ОСЛОЖНЕНИЯ ПРИ ЭКСТРАКЦИИ КАТАРАКТА

Лекция прочитанная доктором Гуден

КОНСПЕКТ.—Автор приводит следующие важные факторы:

1. Образование передней капсулярной синехии при корнеальном надрезе (кератомом) после эвакуации травматического катаракта. Синехии могут быть отделены заблаговременно при помощи тупого ножа после перфорации роговой оболочки острым ножом, на подобие тенотома.

2. Непроизвольный пролапс капсулы при надрезе катаракта:

а) Это явление было приведено как причина глаукомы, в особенности когда необходимо перерезывать непрозрачную капсулярную оболочку после экстракции.

б) Риск симпатической офтальмии.

Пролапс может быть предупрежден:

а) Путем интракапсулярной экстракции.

б) Путем извлечения хрусталика через нетронутый зрачок при помощи капсулярных щипцов с последовательной частичной или полной придектонией.

3. Обсуждено лечение последствий непрозрачного катаракта и описаны разные типы непрозрачной капсулярной оболочки:

а) Непрозрачные волокна хрусталика заточенные между передними и задними остатками капсулы.

б) Серая оболочка сформированная из новых волокон хрусталика от отрывков субкапсулярных клеток.

в) Клетки Эллинга.

- г) Сильно утолщенная капсулярная оболочка, которая являлась следствием экстенсивного кровотечения в переднюю камеру и которая встречалась на пятый день после экстракции.
- д) Толстая оболочка из фиброзной ткани, которая являлась следствием вторжения колобомы радужной оболочки после инфекции во время операции. Фиброзная ткань происходит от нижней поверхности конъюнктивальной локусы и производит вытянутую вверх колобому, которая суживается от сокращения.

При капсулотомии нужно избегать утолщенные связки и разрез сделанный в капсуле должен быть параллельным к утолщенным связкам.

Когда оболочка очень толста и когда имеются признаки ее разрыва от периферического прикрепления при употреблении только одной иглы, можно—

- или 1) употреблять две иглы по способу Бомана;
- или-же 2) произвести операцию Вилера (1939, сборник лекций, стр. 197);
- или-же 3) перерезать толстую капсулю ножом Циглера по способу предложенному автором, а не Циглером.

Опасность произведения капсулотомии при присутствии мягкого хрусталика тоже опасна.

Автор также отмечает, что изредка появляется местная непрозрачность стекловидного тела на месте капсулотомии, даже если и нет придо-циклита.

Capsular complications following cataract extraction have become rarer owing to improved technique in operating. They will become still rarer as time goes on and intra-capsular extraction becomes better known and more widely practised; nevertheless, capsular complications will continue to arise. Many complications of cataract extraction are due to bad operating, but some capsular complications occur in the practice of the most skillful operators and follow an apparently perfect operation.

In this paper I refer almost exclusively to the operation in which the lens is removed from its capsule, an operation that leaves within the eye the greater part of the lens capsule.

Two types of incision are commonly used: one, in the cornea, and the other an incision at the limbus with the formation of a conjunctival flap, and there are certain advantages and disadvantages that attend each method.

If the incision is corneal, the retraction of the divided tissue is most marked at the anterior and posterior surfaces so that when the edges of the wound come together it is the central part, corresponding to the substantia propria, that meets, leaving a wedge-shaped gap anteriorly and posteriorly. The coagulum which is formed causes the edges of the wound to become adherent one to the other. The anterior wedge-shaped gap becomes filled with epithelium and the posterior gap with endothelium from the cells which line the membrane of Descemet. The cicatricial tissue that forms comes from the corneal corpuscles. As the scar develops it extends upwards into the anterior wedge-shaped area and gradually replaces the plug of epithelium that filled the anterior part of the wound, and in a similar way the posterior wedge-shaped area is filled by scar tissue and the endothelial plug replaced.

When the incision is through the limbus, with the formation of a conjunctival flap, there is a similar retraction of corneal-scleral tissue to that which occurs when the incision is corneal as described above, but in this case the anterior area is not filled with corneal epithelium, but by subconjunctival tissue derived from the deep surface of the conjunctival flap.

Corneal wounds have been found filled after twenty-four hours and experimental investigation of the healing of conjunctival wounds shows that the epithelium over the wound is complete in one hundred and twenty hours. Keratome incisions of the cornea are notorious for the rapidity and ease with which they heal; such incisions are very oblique and delicate, but an incision with a Graefe knife can be at right angles to the surface of the cornea and does not heal as rapidly, and as a result epithelium may line the wound and pass into the anterior chamber and indeed completely line it. A similar thing may occur if a closed corneal wound is reopened during the healing process. The result will be a secondary glaucoma and loss of the eye sooner or later. I have had an example of glaucoma that could not be relieved occurring within six weeks of the extraction.

If there is delayed agglutination of the wound at the limbus when a conjunctival flap has been formed then subconjunctival tissue extends between the two sides of the wound and it may produce a vascularized fibrous membrane which fills the coloboma and becomes continuous with the capsular remains. Again, when an intractable iridocyclitis has followed an extraction, there is frequently found imperfect closure posteriorly of the lips of the limbal incision due to an entanglement of the lens capsule. This is not merely due to the presence

of a piece of capsule acting as a foreign body in the wound; the piece of capsule must still be attached to the ciliary body. Incidentally, such eyes are extremely dangerous from the point of view of sympathetic iridocyclitis. Very similar results follow the prolapse of vitreous, a strand of which may be left imprisoned in the operation wound.

It is not suggested that capsule imprisoned in the operation scar always leads to disaster, but at one time there were innumerable irritable red eyes following extraction. Many cases showed a strand of lens capsule passing through the coloboma to the operation scar and it was only when this was appreciated and great care taken to be certain that all lens capsule was returned to the eye that the number of irritable eyes was reduced and posterior capsulotomy became a safe operation, free from anxiety. It took many years to convince ophthalmic surgeons how important it was to be certain that the operation scar was free from imprisoned capsule. This gospel was preached incessantly by William Lang but it took a long time to find the remedy for a complication that might happen to an apparently perfect operation performed by a highly skilful operator. Mr. Morton, an extraordinarily beautiful operator, used, in all cases of cataract extraction, to deliver the lens through a complete and undilated pupil, and in this he was followed by Devereux Marshall. A large proportion of cases were left as simple extractions and those that did not prolapse subsequently gave the best results of all cases of extraction that were done at Moorfields when, as Senior House Surgeon, I had charge of the cataract wards. Here then was the remedy to prevent the unwitting leaving of "capsule in the wound". If the lens were delivered through an intact pupil and care was taken that the iris was perfectly returned to the eye then it was certain that all lens capsule was returned to the eye and it mattered not, so far as the capsule was concerned, whether an iridectomy was performed or not.

The serious complication is, of course, prolapse of the iris, which occurs during the first ten hours after the cataract operation. We knew that, because Morton gave instructions that the cases on which he had operated, between 10 and 11 o'clock in the morning, were to be inspected the same evening, and any prolapsed iris was to be removed there and then. We usually inspected the cases about 5.30 and if prolapse had not occurred then, we looked upon the eye as safe. At the time of the extraction only cases that were apparently unlikely to prolapse were left with an intact pupil; so such cases were picked. In spite of that, prolapse of the iris was common and we were very much bored by having to operate at that time of day when many new cases were waiting for their case-sheets to be made out. Most surgeons look upon prolapsed iris after extraction as a serious matter.

METHODS OF OPERATION THAT MODIFY AFTER-CATARACT

After-cataract does not follow an intracapsular extraction which has been successfully performed.

The use of capsule forceps when the lens is extracted from its capsule membrane certainly does leave a much thinner capsular membrane, sometimes merely a crinkled posterior capsule in the pupillary area, and often one that is transparent and smooth.

There is one condition in which capsule forceps are essential, and that is those cases in which the anterior capsule of lens has become dotted. If the anterior capsule is not removed in such cases a subsequent needling may fail to give a clear gap, as the dotted capsule will remain in the middle of the pupillary area in spite of being temporarily pushed aside by the discission needle.

I do not know if capsule forceps are in common use. English models are usually very clumsy, with large rough teeth, but those made by Greishaber from Vogt's specification are beautiful. Attempts have been made to copy them in London, but they are comparatively gross.

There is much to be said for early needling and Herbert in India operated ten days after extraction. This seems very early, but in India unless the needling were done before the patient left hospital there was no other chance owing to the distance from which patients came. In England the needling may be done a month after the patient has returned home, that is six weeks or so after the extraction. The posterior capsule is still elastic and will gape when an incision is made in it; if, however, we wait until it has become opaque and degenerated, then it becomes like a piece of cigarette paper and will not gape when incised. Bowman first pointed out the elasticity of the lens capsule and the accommodation hypothesis of Fincham depends on this feature.

THE RELATION BETWEEN CAPSULE ADHERENT TO THE OPERATION SCAR AND GLAUCOMA

This relation was thoroughly and extensively investigated by Natanson, who published his results in 1889, and Treacher Collins in 1890.

It has already been noted that glaucoma following a cataract extraction may be due to corneal epithelium invading the anterior chamber and subsequently lining it, and this is more likely to occur when the incision is corneal.

When the incision is at the limbus with the formation of a conjunctival flap the lens capsule may become adherent to the operation scar, as also it may be adherent to a corneal section. In those cases that develop glaucoma, the angle of the anterior chamber was closed by the adhesion of the root of the iris to the posterior surface of the cornea, and in all these eyes there was an adhesion of the lens capsule to the operation scar. In some cases, in spite of the adhesion of the lens capsule to the scar, glaucoma did not arise until a needling operation was performed, so that if an adherent capsule does not produce glaucoma, at any rate it predisposes to glaucoma by a shallowing of the anterior chamber.

ANTERIOR SYNECHIA AFTER A LINEAR EXTRACTION OF A SOFT CATARACT OR AFTER EVACUATING A TRAUMATIC CATARACT

(1) This is less frequently seen since anterior chamber washout became more usual.

(2) Lang's incision in the upper part of the cornea was the result of his experiment with Fukala's operation for high myopia. He did 80 cases before he abandoned the operation largely because of the frequency of detachment of the retina. This was one of the early observations of the connexion between dissection of a lens and detached retina. It is now appreciated how often detachment of the retina occurs years after an operation for, say, zonular cataract. Lang introduced the operation of "curette evacuation" through an incision in the upper part of the cornea, because if an adherent or prolapsed capsule followed, he was able with Lang's twin knives to separate capsule that was adherent to, or prolapsed through, the cornea. Previous to the adoption of this plan of operation, lens matter was commonly let out by incision at the limbus down and out. The reason for choosing this site was that during an imperfect anæsthesia with chloroform, the eyes turned upwards and this was the site most easily available for incision. It needed great skill on the part of the anæsthetist to arrange that the depth of anæsthesia was such that the eye turned downwards allowing the upper part of the cornea to be available for operation. As the result of making an incision down and out at the limbus, the capsule not infrequently prolapsed, and also the iris. This was very difficult to deal with and, in the case of prolapsed capsule, impossible. Many bad results from operation for zonular cataract are due to these accidents. By placing the incision in the upper part of the cornea half-way between the margin of the cornea and the centre, it becomes possible to divide this synechia by means of the twin knives. If, however, the prolapse of capsule occurred at the periphery, especially down and out, then it was impossible to divide the synechia, and the eye was left for ever with a capsule synechia which, even if the eye settled down, was in danger of subsequent glaucoma, especially if a dissection of capsular membrane became necessary later on.

OPAQUE CAPSULAR MEMBRANE

There are several types of opaque capsular membranes, usually called "after-cataract":

(1) That in which the anterior and posterior portions of the lens capsule become more or less agglutinated, imprisoning soft cortical lens matter.

(2) An opaque membrane due to the proliferation of anterior capsule cells forming greyish lens fibres as a sheet filling the pupillary area.

(3) Elschnig's cells due to a globular degeneration of new lens fibres usually attached to a posterior iris synechia.

(4) A modified and much thickened capsule, with a felted surface following an extensive hæmorrhage into the anterior chamber about one hundred and twenty hours after the extraction.

It is remarkable that blood that remains in the anterior chamber immediately following the extraction disappears very rapidly, but the blood that appears about the fifth day takes, sometimes, several weeks to disappear.

This blood, I think, always comes from the conjunctival flap, possibly from the vessels that have invaded the limbal incision. I have watched the hæmorrhage occur, and it falls downwards through the anterior chamber in a worm-like way.

(5) A thick membrane formed of fibrous tissue which follows the invasion of the coloboma of the iris after infection at the time of operation. The fibrous tissue comes from the under-surface of the conjunctival flap and causes an up-drawn coloboma which is also made narrower by its contraction.

Very little investigation has been made on the composition of capsular membranes. One was published in 1900 by W. H. Bates, who is now better known in connexion with a method of treatment to which his name is attached.

of a piece of capsule acting as a foreign body in the wound; the piece of capsule must still be attached to the ciliary body. Incidentally, such eyes are extremely dangerous from the point of view of sympathetic iridocyclitis. Very similar results follow the prolapse of vitreous, a strand of which may be left imprisoned in the operation wound.

It is not suggested that capsule imprisoned in the operation scar always leads to disaster, but at one time there were innumerable irritable red eyes following extraction. Many cases showed a strand of lens capsule passing through the coloboma to the operation scar and it was only when this was appreciated and great care taken to be certain that all lens capsule was returned to the eye that the number of irritable eyes was reduced and posterior capsulotomy became a safe operation, free from anxiety. It took many years to convince ophthalmic surgeons how important it was to be certain that the operation scar was free from imprisoned capsule. This gospel was preached incessantly by William Lang but it took a long time to find the remedy for a complication that might happen to an apparently perfect operation performed by a highly skilful operator. Mr. Morton, an extraordinarily beautiful operator, used, in all cases of cataract extraction, to deliver the lens through a complete and undilated pupil, and in this he was followed by Devereux Marshall. Bowman first pointed out the elasticity of the lens capsule and the accommodation hypothesis of Fincham depends on this feature.

THE RELATION BETWEEN CAPSULE ADHERENT TO THE OPERATION SCAR AND GLAUCOMA

This relation was thoroughly and extensively investigated by Natanson, who published his results in 1889, and Treacher Collins in 1890.

It has already been noted that glaucoma following a cataract extraction may be due to corneal epithelium invading the anterior chamber and subsequently lining it, and this is more likely to occur when the incision is corneal.

The instrument is a Graefe knife with a blade 18 mm. long and 1 mm. wide.

FIG. 2.—Discission knife for after-cataract. Blade is 18 mm. long and 1 mm. wide.

The surgeon stands at the head of the table and a little to the left of the eye to be operated on. A speculum is introduced and the eye is fixed by grasping the conjunctiva and subconjunctival tissue below the cornea at a point diametrically opposed to the point where the knife is to enter the cornea. The fixation forceps is held in the left hand without the slightest pressure on the eyeball.

The handle of the knife is taken most delicately between the pulps of the forefinger and thumb 2 inches (50 mm.) from the point of the knife, and care is taken that there is no tendency of the finger to wrap itself round the handle. This would render the execution of the technique impossible.

The eye looks slightly downwards, and the point enters the upper part of the cornea 1 mm. from this limbus, in front of the coloboma (when an iridectomy has been made at the time of the lens extraction). The incision is planned to go through the heaviest bands if possible, but the bands can be cut at any angle; and it is well to carry the incision into the coloboma.

The knife point is carried deliberately across the anterior chamber and behind the inferior portion of the iris, and carefully brought in contact with the capsular membrane. One can take all the time one wants in this part of the procedure, provided the fixation forceps and the knife are held in absolute relaxation. The rest of the operation is done speedily so that the incision is completed before the capsular membrane begins to relax from division. By an absolutely simple movement on the part of the surgeon the point and cutting edge of the knife blade are put through just the sort of excursion that is needed to produce a long-drawn incision in the membrane without enlargement of the surface wound in the cornea.

FIG. 3.—Mechanics of discission. Finger and thumb hold knife lightly, and are carried along arrowed line. Knife point courses in vitreous body along dotted line. C gives view of back of knife as held in fingers.

(Figs. 2 and 3 are reproduced from "Secondary Cataract Opening by Single Straight Incision" by John M. Wheeler, *Trans. Amer. Acad. Ophthalm. Oto-Laryng.*, 1924, p. 149.)

From the position in which the knife is held with the point in gentle contact with the capsular membrane, the part of the knife handle between the pulps of the finger and thumb is carried in a straight line by a free rapid movement of the arm, without any change in the position of the hand and wrist. By this movement the blade is made to slip in and out of the vitreous without any interruption in the sliding motion on the membrane, and the non-cutting edge of the blade receives gentle pressure against the cornea until the blade slips out of the corneal wound, usually without loss of aqueous (fig. 3). As the end of the forefinger and thumb are carried along a straight line from position A to position B, the knife handle changes position as though working freely on a pin passing through the knife handle set in the pulps of the forefinger and thumb. This imaginary pin passes straight along the course

THE OPERATIVE TREATMENT OF AFTER-CATARACT

An operation was described by Sir William Bowman on May 24, 1853. He entitled his paper: "On the Use of Two Needles at Once in Certain Operations on the Eye, Especially in Those for Capsular Cataract and Artificial Pupil".

(1) This operation has been recently revived, but I have no personal experience of it. This operation overcomes difficulties met with in thickened capsules and those that tend to become detached at the periphery. When this occurs the surgeon is placed in an impossible position as the mere displacement to one side of the opaque membrane is never permanent, in that it always returns to its original place.

If two needles are brought to bear on the opaque capsule from different sides of the cornea or sclerotic, each furnishes the other with a point of resistance, and the capsule may be torn open or cut at pleasure in almost any direction, and generally without any drag on the neighbouring vascular structures.

A great advantage of this mode of operating is that it may be at once adopted in any case where, on trial, a single needle is found to be insufficient to effect the laceration of the obstructing membrane. It is usually possible to decide before setting out upon an operation whether it may be carried out with one needle only, but on other occasions the needle alone can afford a correct intimation of its texture.

Bowman devised a needle, known as the "stop needle", which is now hard to come by. One uses it now, not because of the stop, but because it is perfectly cylindrical and the cutting portion makes a hole into which the shank exactly fits. It may be remarked here that a needle that has been re-ground is of no value for a discission, as the cutting part has been reduced and no longer makes a perforation that will admit the shank of the needle precisely, so that it jams. This not only bruises the eye, but causes a wrinkling of the cornea which very much interferes with the view the surgeon has of the membrane and the effect of his endeavours to cut it. To avoid the chance of inadvertently penetrating too far with one of the needles, whilst the attention is engaged on the other, the stem of the needles is made thicker from the handle up to within half an inch of the point; in no case is it necessary to enter the instrument beyond half an inch in length.

(2) For a capsular membrane that is not unduly tough or, what is more important, movable or likely to become detached, I personally use a Ziegler needle and preferably one made by Grieshaber of Schaffhausen.

These are made very precisely and the cutting portion makes an incision that just admits the shaft of the needle so that it may be partially withdrawn from the eye or pushed farther into the eye without fear of loss of aqueous.

Furthermore, if it is returned to Grieshaber to resharpen, they slightly reduce the diameter of the shaft so that the cutting portion still makes an incision into which the shaft fits precisely.

I do not use the instrument in the way described by Ziegler who introduced the instrument for the performance of iridotomy in cases in which, after cataract extraction, the iris has become drawn up to the scar of the extraction incision. Choosing a portion of the capsular membrane free from toughened bands I puncture it parallel to the surface of the vitreous and then, pushing on the cutting portion of the needle as much as possible between membrane and vitreous face, I again puncture the membrane and then depress the handle of the instrument so as to raise the capsular membrane forwards and then cut upwards either by a dragging movement or a sawing movement. In that way a triangular piece of the capsular membrane is cut with the base below (fig. 1).

FIG. 1.—Method and result of discission with Ziegler's knife.

Given a good cutting instrument quite tough membrane can be cut.

(3) Wheeler has devised a most useful procedure for dividing a capsular membrane and it is of great value in dealing with tough membranes. Further, it is the best method I know for performing an iridotomy after a removal of the lens.

I was interested by the remarks Mr. Goulden made at the end of his paper in regard to the thickening of the anterior vitreous after capsulotomy. I used to think that once there was a good gap in the capsule it would never close but rather to my dismay not long ago I had one which did close and I had to ask Mr. Goulden about it. He and I thought the eye would never get better vision. However, I tried once more and got a good gap through the apparently opaque layer of vitreous and, in the end, I achieved a definite improvement on my original result.

Professor W. J. B. Riddell: With regard to the position of the stop on the needle, Mr. Goulden would like to have it $\frac{1}{4}$ inch from the point, which is 12.5 mm. Should it not be rather less than $\frac{1}{2}$ inch, because this would take it right across the anterior chamber before the stop would come into action; the diameter of the cornea being about 11.5 mm.?

Mr. H. M. Traquair: Mr. Goulden did not mention the method, used frequently by Marshall, of dividing the capsule with the knife as it passes across the anterior chamber. In Edinburgh about 1910 discission was the common practice, but one gave up the cystitome after the first year or so for the capsule forceps, because it seemed to be a great advantage to be able to remove the whole of the anterior capsule. I would like to give credit to Dr. George Mackay of Edinburgh for the invention of a good pair of capsule forceps which, if properly used, enabled practically the whole of the anterior capsule to be removed so that none, or very little, of the soft lens matter remained, and the need for subsequent needling was very much diminished.

The next step, and one which developed in Edinburgh because we had learned to use the capsule forceps, was the introduction by Sinclair of the intracapsular operation. Edinburgh is strongly in favour of that operation because it is regarded as not only the easiest but the safest method of cataract extraction.

I whole-heartedly support the view that discission is by no means to be given up. The late Sir George Berry advocated discission with two needles by passing them through the membrane and then turning the shanks upwards so as to pull the capsule apart, the advantage of two needles being that traction on the ciliary body was largely, if not altogether, avoided. Latterly, when doing discission I have used two Ziegler needles, introduced and then turned so that the cutting edges point backwards with the points crossing in the middle of the membrane. Then, when the shanks are approximated, there is even less danger of traction as a cutting action is obtained if the needles are sharp.

I have often used Wheeler's knife but it seemed to plunge too deeply into the vitreous. Apart from lamellar cataracts, and so on, my Ziegler's and Wheeler's knives have lain unused for a good many years now. In using Wheeler's knife Mr. Goulden indicated that its point should be directed vertically downwards before turning the handle up. I feel that one needs to be careful to avoid the danger of traction when using a single instrument. The membrane is searched for a thin part and the knife inserted opposite that weak spot so that it can be passed across the anterior chamber to pierce the capsule at that point. There is no fixed rule that the incision should be vertical.

An annoying occasional complication in the old days was an adhesion of the vitreous to the wound causing an opacity like a strand of seaweed which hung down and waved before the patient's sight, creating a great deal of annoyance, and which it was impossible to remove.

Mr. H. B. Stallard: Mr. Goulden has spoken of the danger of strands of vitreous coming into the wound on withdrawing the knife-needle after the capsulotomy. There is an Indian practice whereby, after the knife has made the incision through the capsule, it is passed on to the filtration angle opposite the site of entry, turned round sharply several times and then withdrawn quickly, thus disentangling any strands of vitreous from the point of the knife-needle. The principle is much the same as when withdrawing a spoon from a jar of honey.

Mr. J. G. D. Currie: How much real damage occurs when an incision actually goes rather farther back into the vitreous than we usually do nowadays? I know that the general practice in the past was to cut rather far back into the vitreous when needling, and certainly in Wheeler's operation this is almost bound to be done. The practice is now to pick up the capsule and move anteriorly, but sometimes this gives one very restricted room if the capsule is rather elastic. It has always been a moot point in my mind whether one should cut back or not on these occasions.

Mr. M. H. Whiting: The double needle operation offers great advantages for capsulotomy, but there is no need to use two needles if the capsule is thin and it is desired to operate three or four weeks after the cataract extraction, which is what I prefer to do.

Mr. Goulden referred to opaque vitreous coming up into the capsular opening after capsulotomy. I can only remember one occasion on which that happened and I am certain that in that case it was actually opaque vitreous from cyclitis beforehand, which did not oppose so much obstruction to the light when the surface of the vitreous was flat, but when the little knob of vitreous came forward through the opening in the capsule it was a much greater obstruction. The vision of this particular patient was reduced about two lines instead of being improved. The interesting point was that I watched that patient for some time afterwards and the little knob of vitreous actually flattened down and became level with the surface of the capsule and the vision improved correspondingly until finally I got the vision I anticipated I should get from the capsulotomy.

Mr. B. W. Rycroft: Has any member had experience of examining the lens capsule with ultraviolet radiation? A short time ago I saw a demonstration in a foreign clinic where the Philips' ultraviolet lamp was used. It was very uncanny in a darkened theatre to see the rows of gleaming white teeth surmounted by pairs of mature soft white cataracts. The practical value is that a dislocated lens in the vitreous or a fine strand of capsule is very visible against a dense black background. It

indicated by the arrowed line in the slide, and the knife slides in and then out as it goes across the eye, and the operation is done.

The result of this act is a straight incision which gradually opens up and never has a tendency to close. Manifestly the opening must be in the visual line, but the width is not important as long as it is properly placed. The effect of severing a band is shown by a slight angulation in the edges of the opening where the band is cut. There is no membrane, no matter how heavy the bands, that will not open out freely by this method if the knife and the technique are correct.

In cases in which there is capsule imprisoned in the extraction wound, especially if considerable in amount, there is the risk that glaucoma will occur as a result of capsulotomy. This was especially the case when the discission needle was not used as a cutting, but as a tearing, instrument and in the days when less care was taken to prevent capsule becoming imprisoned in the wound and its danger and significance were not appreciated, and a rough use of a discission needle was common. I have seen the most lamentable results. In fact discission was looked upon as an operation to be avoided if possible. Many surgeons would not touch an eye that had 6/12 of vision and as a house-surgeon one was not expected to admit cases for capsulotomy that had a vision of 6/18.

OPAQUE CAPSULE IN THE PRESENCE OF LENS REMAINS

After an extraction of a senile cataract soft cortex is frequently left behind, sometimes in fair amount, although this is less frequent since the routine wash-out of the anterior chamber. Masses of opaque lens remains become imprisoned between portions of anterior and posterior capsule, but as these are so often behind the iris they are not of importance in this respect. It is rather those lens remains in the pupillary area that are of importance. Patience must be practised and due time allowed for these remains to absorb before a discission is made, because if the posterior capsule be incised in the presence of soft lens remains, trouble will be experienced with a mixture of vitreous and opaque lens matter. If the process of absorption is unduly slow, then the lens matter may be broken up with a needle without perforating the posterior lens capsule and another period allowed to elapse so that the lens material may absorb. It is notable how much frequent and regular hot bathing of the eye will assist this absorption. Then, when all lens has disappeared, the posterior capsule may be divided.

THE PROLAPSE OF VITREOUS INTO THE ANTERIOR CHAMBER AFTER A NEEDLING OPERATION

If vitreous has escaped during a cataract extraction, a thicker or thinner strand becomes imprisoned in the operation scar, and when a vigorous needling has been performed a strand of vitreous follows the withdrawal of the needle and is imprisoned in the needle puncture. In these cases glaucoma may be the result either of the extraction or needling, and a pathological examination will disclose a shallowed anterior chamber and a blocking of the angle much as in those cases in which the capsule of the lens is imprisoned in the extraction scar. Apart from these accidents, vitreous is always prolapsed into the anterior chamber even in the most gentle and best planned needling of the posterior capsule. This prolapse is never extensive when the needling is properly performed, but it may always be seen with the slit-lamp and invariably some small brown particles of uveal dust are found mixed with the greyish flocculent-looking prolapsed vitreous. The prolapsed vitreous I think tends to become less in amount as time goes on. I have never seen vitreous prolapsed in a gross amount into the anterior chamber as a result of needling in a case uncomplicated by the adhesion of capsule to the operation scar.

OPAQUE VITREOUS FOLLOWING CAPSULOTOMY

I have, on a few occasions, seen the vitreous in the immediate district of a capsulotomy become opaque and thus interfere with vision and lead to a disappointing visual result, and this opacity has remained permanent. The flocculent mass of vitreous in the capsular opening may be found if the operation of needling is performed during an attack of cyclitis.

Mr. Harold Ridley: In modern extracapsular cataract extractions the middle of the anterior layer of the lens capsule is generally removed with capsule forceps, instead of being simply incised with a cystitome or the point of the cataract knife. Consequently complications due to a dense capsule is much less frequent and often an acuity of 6/6 is obtained without division of the delicate posterior layer. In his paper Mr. Goulden did not mention how he dealt with dense bands in the capsule but I believe that his policy is not to attempt division of these but to perform the capsulotomy through an adjacent thin area.

Mr. Arthur Lister: I have had the privilege of watching Mr. Goulden do a Wheeler's iridotomy and it is worth seeing the crisis of the operation as he poises with the knife in position and then the blade goes back like lightning through the capsule.

Melanotic Adamantinoma of the Mandible in a Child Aged 5 Months.—S. H. WASS, M.S., F.R.C.S.

ON August 30, 1947, Dr. Rosenberg of Worthing referred to my Out-patient Department at Guy's Hospital a female child, aged 5 months, with a swelling of the right lower jaw. This swelling had been first noticed six weeks previously and the mother was of the opinion that it had increased rapidly in size during this time. At first the swelling did not appear painful, but more recently it had seemed tender to touch and the child had become fretful though the general health of the child was satisfactory.

On examination there was a visible external swelling in the region of the right lower jaw without any change in the overlying skin. Inspection within the mouth (fig. 1) revealed a

FIG. 2.—Intra-oral radiograph showing expansion and thinning of outer table of mandible with translucent zone apparently containing temporary canine tooth.

smooth, ovoid swelling of the outer table of the right side of the mandible in the 5-1 region. The lower border and alveolar margin of the jaw were not involved and there was no expansion of the inner table. The right lower central incisor (temporary) was the only tooth erupted. The swelling was firm in consistency, well defined at its edges and had a smooth surface. It was not tender and there was no fever. The soft tissues of the cheek were normal and there was no enlargement of the cervical glands.

The intra-oral radiograph (fig. 2) showed expansion of the outer plate of the mandible in

is possible to get this lamp in England, and I feel it has a practical application in a small group of cases.

The President: The Grieshaber capsule forceps is certainly a beautiful instrument and works exceedingly well for the extracapsular operation.

I should like to ask Mr. Goulden whether, in the case of capsular strands remaining after extraction, it is not at least as important as the attachment back to the ciliary body that these strands should not reach the surface between the lips of the wound, because in such a case a track would exist along which infection could reach the interior of the eye from the surface.

Mr. Charles Goulden: I do not think I know what the mechanism of the consequence of capsule in the wound is, why it should keep an eye irritable. I had not looked upon it as being infective. Does anybody know the reason why an eye should remain so irritable with capsule attached to the ciliary body? Is it infective?

Mr. E. Wolff: Does it not leave the way permanently open? So long as there is capsule in the wound and there is no proper healing, infection can, in time, travel down the wound.

Mr. Goulden: In answer to Mr. Ridley: I think it important that any incision made in the capsule remaining after extraction should be through thin membrane and parallel to thickened bands. No attempt should be made to cut thickened bands.

Dealing with Professor Riddell's point, let me say that I copied the description of Bowman's needle from his original paper, in which the thinner part of the needle from the point to the thicker part is described as $\frac{1}{2}$ inch long.

Mr. Traquair spoke of the anterior dipping of the knife in the operation of extraction, so as to perforate the anterior lens capsule. I first saw it done by Morton and Marshall and I think it a mistake. The pioneer in England of the use of capsule forceps was John Couper. Mr. Traquair mentioned Dr. Mackay.

Mr. Traquair: In Edinburgh!

Mr. Goulden: I do not know who was the first in the field, Couper or Mackay. I think Couper's forceps of great use in dealing with prolapsed iris after an accident. For the purpose for which they were invented they are coarse and clumsy and not to be compared with Vogt's capsule forceps made by Grieshaber.

I agree with what has been said in regard to intracapsular extraction, which I think, without doubt, is going to be the operation of choice.

I am much obliged by Mr. Whiting giving us the benefit of his experience. I understand he used the double needle only when dealing with difficult cases.

Then Mr. Currie spoke of the question of the depth to which one should dip the needle. On general principles it seems to me one should disturb the vitreous as little as possible. Hence the method of sliding the needle between the capsule and the face of the vitreous. I would not say more than that. The vitreous is not often dislocated very much into the anterior chamber, even when the needle is roughly used.

In the presence of a tough capsule, with the ordinary operation with a needle, you are between the devil and the deep blue sea! If you try to needle the capsule in the ordinary way it is impossible, and you will partially dislocate the capsule and leave no gap. The double needle operation may be used, but of that I have no experience. The use of Wheeler's operation disturbs the vitreous very little.

Mr. Currie: That is what I was interested in, that it did seem to disturb the vitreous so little.

Mr. Goulden: In reply to Mr. Rycroft, the only experience I have had as to the use of ultraviolet radiation was when I saw Kalt in Paris, at the age of 78, performing intracapsular extractions. He demonstrated, if the lens became dislocated into the vitreous, that with ultraviolet light the lens was easily seen. I have never, apart from this occasion, seen anyone of 78 years operating for cataract.

The post-operative course was undisturbed and healing of the mucous membrane took place by first intention. The child was examined again two months after operation (December 1947) when the jaw was firm; radiographs showed complete re-ossification of the mandible. There was no clinical swelling and the child was in good health. The ultimate prognosis with regard to this rare tumour cannot be assessed. A search of the literature reveals only one similar case previously recorded (Mummery and Pitts, 1926). This case was identical in all its features with the one presented to-day and was recorded to have survived four years after operation without any signs of recurrence.

I am indebted to Miss S. Treadgold, of Guy's Hospital, for the water-colour drawing and to Mr. J. E. Hutchinson of the Department of Dental Medicine, Guy's Hospital, for the photomicrographs. My thanks are also due to Professor M. A. Rushton for his help and interest in the diagnosis and treatment of the patient.

Electronic Apparatus for Immediate Visual Recording of Pulse Rate. [*Abstract*]

By W. ROTHERAM, M.D.S., M.B., Ch.B.

(*Late Major, Officer Commanding a Surgical Team in the Middle East*)

A SERIES of experiments was outlined, using electronic methods and principles—the object being to devise apparatus which would give a continuous visual recording of pulse rate on a scale marked in beats per minute and applicable during operation upon major surgical cases. The experimental stages were reviewed and the reasons for the adoption of the particular circuit arrangements were explained.

The apparatus was then described in its final form—constructed as one unit—the component parts and individual circuit sections consisting of the following:

- (1) The arrangement for initial pick-up of the impulse.
- (2) An amplifier section.
- (3) A "Limiter" circuit which it was necessary to include to ensure that in spite of variations in volume and amplitude of the pulse, a constant voltage would be "fed" into the succeeding stages of the apparatus.
- (4) A Diode Rectifier—to turn the alternating impulse into a unidirectional one.
- (5) A recording valve—a final stage consisting of a voltage amplifier and milliammeter (with a full-scale deflection of one milliamp).

The electronic principles underlying the properties of a condenser and resistance were described—these being an essential (though small) part of the circuit arrangement. This was in connexion with that section of the apparatus which actually carried out the "count" of the impulses—and in relation to that property of a condenser and resistance known as a "Time-Constant"—this being the time taken for a condenser to charge when associated with a particular resistance.

The panel controls were then described—the most important one consisting of a resistance (variable) included in the Diode circuit (*see* 4)—this variable serving to "open" or "close" the scale of the instrument, e.g. 40 to 180 beats/min. or 70 to 90 beats/min.—several ranges being available by adjustment of this control. The methods used to calibrate the instrument were given.

The method of operation of the instrument was described including the adjustment of the panel controls for the individual case.

Finally the uses of the apparatus were summarized as follows:—

- (1) In prolonged and extensive surgical procedures especially in cases of serious injuries.
- (2) In anaesthesia—particularly of long duration.
- (3) In any other cases where second-to-second observation of pulse rate is important.

the region of the swelling. The bone of the outer table was extremely thin and was absent in one place. Deep to the outer table was a rounded, clear, translucent zone which appeared to contain the temporary canine tooth. On these radiographic findings a provisional pre-operative diagnosis of a dentigerous cyst was made, although the rarity of such a cyst in relation to a deciduous tooth was fully appreciated.

The child was admitted to hospital but owing to intercurrent infection operation was delayed until October 1947. During this period in hospital the swelling of the jaw showed no increase in size and the physical signs remained unaltered. Operation was undertaken under intratracheal anaesthesia by Dr. J. Gordon. After injection of local anaesthetic solution a flap of mucous membrane was raised from the outer side of the mandible over the tumour. The outer surface of the tumour was covered by a thin layer of bone, but in two places the bone of the outer table had completely disappeared and the fibrous capsule of the tumour was visible. The thin bone was removed from the surface of the tumour and the unerupted deciduous canine and lateral incisor teeth were found to have been pushed outwards by the tumour and not to be contained within it as the radiographs had suggested. The tumour was encapsulated and shelled out easily from the mandible. At the conclusion of the operation the mucous membrane flap was sewn back in position.

The tumour removed from the jaw was solid, ovoid in shape and measured 2 cm. by 1.5 cm. The cut surface was firm, white in colour, and showed a large patch of bluish-black pigmentation. I am indebted to Dr. S. de Nevasquez for the following pathological report:

"The specimen is a smooth solid oval tumour 2 by 1.5 cm. of uniformly firm consistency, the cut surface of which is mottled by flecks of black pigment. Microscopically the tumour consists of

FIG. 3.—Photomicrograph ($\times 87$) showing alveolar arrangement of epithelial cells in the centre of the tumour.

FIG. 4.—Photomicrograph ($\times 325$) showing alveoli in which melanin has been produced.

nests of solid masses of epithelial cells, predominantly of basal-cell morphology, embedded in a dense fibrous stroma. The surface of the tumour at one point is covered by stratified epithelium which merges into tall columnar epithelium, composed in a single layer. This surface epithelium appears to dip into the interior where it becomes pleomorphic, merging into typical basal-cell strands and forming alveoli with clear central spaces surrounded by single-layered cubical cells with abundant cytoplasm, containing granules of brown or black pigment, which is melanin. The melanin-containing epithelium, which is mainly alveolar, appears to merge into the solid basal-cell type. In addition, there are foci where the cells are stellate and resemble ameloblasts.

"I think that the tumour is a solid epithelial odontome (adamantinoma or ameloblastoma) arising from the germinal layer of the gingivo-dental tract and producing a varied morphology in its epithelial elements, including melanoblasts, by divergent differentiation. The latter phenomenon (melanin formation) is most unusual, if not unique, in such tumours." (Figs. 3, 4.)

pigmentation in only 2 out of 500 12-year-old children, whereas in Maldon it is very common. The great majority of observers have been able to find mottling and pigmentation in the permanent dentition only, but Marshall Day (1940) has recorded a high incidence of mottling in deciduous teeth in one district in India.

It is, I think, established beyond any doubt that there is no relationship whatever between mottling and freedom from or susceptibility to caries. If one examines in South Shields a sufficiently large number of children showing enamel mottling and compares them with an equal number of South Shields children showing no sign of mottling, the incidence of caries will be found to be precisely the same in the two groups. Similarly, a given number of, say, six-year molars in South Shields showing mottling will be found to show no more and no less caries than the same number of unmottled six-year molars in South Shields—assuming, of course, continuous residence in the area by all the children concerned. This is, I think, a little surprising. It might have been expected that when a substance like fluorine produces two effects on the teeth, namely, mottling and reduction in caries liability, there would be some connexion between the two effects, but apparently there is none whatever.

Those who have subjected mottled teeth to histological examination seem to be agreed that mottled enamel is defective in its structure. Lady Mellanby (1934), for example, said "The prisms are imperfectly calcified, . . . the interprismatic substance is also deficient", whilst McKay (1929) went so far as to say that mottled enamel is "the most poorly constructed enamel of which there is any record in the literature". On the other hand, King (1944), on the basis of clinical examination of Maldon teeth, has recorded his view that, even when mottled, they are often of good structure and his figures make it clear that, in his opinion, the first permanent molars which he saw at Maldon tended to be of better structure than those which he saw in the rural parts of the Island of Lewis.

Fluorine is by no means a rare element, though I was greatly surprised to see it stated in a recent American technical journal that it is about as abundant as nitrogen or carbon. It is coming to be used very widely in industrial processes, and one of the methods employed in separating the isotopes of uranium for the atomic bomb involved the use of a fluorine compound. In this country there seem to be few communities of any size which are dependent on a water supply containing significant amounts of fluorine. Most of the larger cities get their water from moorland gathering grounds, and those waters have little chance of picking up fluorine. Those fluorine-free waters are usually soft, whereas the deep well waters in which fluorine is more likely to be found are often hard. One has, therefore, to meet the argument that the caries-inhibitory effect of waters containing fluorine may be due to hardness and not to fluorine, but I should be sorry to think that there is still any widespread belief that caries incidence is related to hardness or softness of water. In any case, there is convincing evidence from America to show that waters with caries-inhibitory properties vary so widely as regards their hardness and contain salts of all kinds as to rule out the possibility of any ingredient other than fluorine being the caries-inhibiting factor. In a symposium published by the American Association for the Advancement of Science (1946) there is a particularly convincing set of Tables, giving a detailed analysis of the water supplies of 21 towns in the U.S.A., with records of the incidence of caries and of dental fluorosis in those towns.

The fluorine content of articles of diet other than water is, generally speaking, low. An exception is tea leaves, which may contain substantial quantities; the highest of which I have seen a record was almost 1,800 parts per million. Even so, however, the amount of fluorine which one could obtain from tea would be very small. The fluorine content of fish is relatively high; a common value seems to be about 7 parts per million, but presumably a great part of that would be concentrated in the bones which would not, except in the case of the smaller fish, be eaten. The inhabitants of Tristan da Cunha, who seem fated to be quoted in every discussion about dental caries, have practically no fluorine in their drinking water, but their freedom from caries has been attributed to the large part which fish plays in their diet, and which is presumed to supply them with an appreciable amount of fluorine.

Having regard to the fact that marine products tend to have a considerable fluorine content it is rather strange that, so far as I know, no one has ascertained and recorded the fluorine content of cod-liver oil. Is its fluoride content sufficiently high to account for any beneficial effect it may have in inhibiting caries? It may be that the technical problem of estimating fluorine in an oil is a difficult one, but it would be of interest to know what the content in cod-liver oil really is.

The only other constituent of our diet which seems liable to contain any great proportion of fluorine is baking powder. In Nature, fluorides are usually found in association with phosphates, and certain baking powders contain a great deal of phosphate. I understand that those powders have tended to contain so much fluorine that the Society of Public

[February 23, 1948]

The Inhibition of Dental Caries by Fluorine

By ROBERT WEAVER, M.D., F.D.S.

AINSWORTH (1933) described the appearance of teeth observed by him in the Maldon district of Essex, where the water contains about five parts per million of fluorine. For many years previously there had been much speculation, particularly in America, as to the cause of mottled enamel. Many people suspected that the mottling was produced by some substance in the drinking water, though it is of interest to note that one writer in 1926 suggested that it might be caused by a deficiency of fluorine in water. However, about two years prior to the publication of Ainsworth's paper, it was conclusively proved that endemic mottled enamel was caused by the presence of a substantial amount of fluorine in drinking water, and Ainsworth showed that this state of affairs existed in the Maldon area. He observed that the incidence of dental caries was distinctly low in the children whom he examined, but his reference to that point takes up only about four lines in an article of seventeen pages. This is not surprising. It was not then realized that very much lower concentrations of fluorine could inhibit caries, and the readers of Ainsworth's paper, looking at the really admirable accompanying pictures of Maldon teeth, might well have said to themselves: "If this is the price which has to be paid for a lowered caries incidence, then the price is much too high." I understand that this is the view taken by quite a number of residents in the Maldon district, and that it is not unusual for young people in that area to demand that perfectly sound anterior teeth be extracted because they are so unsightly.

During the five years or so preceding the outbreak of World War II, there was an accumulation of evidence indicating that inhibition of caries could be produced by concentrations of fluorine which were too low to cause the unsightly appearance observed in teeth at Maldon and elsewhere. The person who, more than anyone else, deserves the credit for this work is Trendley Dean of the United States Public Health Service. In 1938 he showed the inverse relationship which exists between endemic dental fluorosis and dental caries prevalence, and during the next few years he, in collaboration with various colleagues, published a long series of papers which left no room for any reasonable doubt as to the caries-inhibitory effect of fluorine. When in 1944 I referred to the low incidence of caries in certain north-east Durham areas as being due to a factor F, which was probably fluorine, I did not seriously doubt Dean's conclusions; I was merely being ultra-cautious. The evidence which has accumulated since then has, however, convinced me that there is no need any longer to suspend judgment on this point.

It may be well to mention that, when we talk of fluorine in water, we are really thinking of fluoride. The other elements which combine with fluorine to form fluorides have different atomic weights, and so the amount of fluorine in 1 gramme of, say, fluor spar (calcium fluoride) is by no means the same as the amount in 1 gramme of sodium fluoride. Where quantitative measurements are concerned, we accordingly have to speak in terms of percentages or parts per million of fluorine, and not of fluoride.

It is interesting to speculate as to whether a concentration of, say, 1 p.p.m. of fluorine in water will always produce the same effect on the dental tissues, regardless of the other element with which it is combined to form a salt or regardless of the presence or absence of other substances in the water supply. Dean (1938) at one time held the view that other constituents of drinking water might perhaps have a synergistic action with the fluoride, but my impression is that he was merely refraining from ruling out any possibility, and that he really believed that fluorine produces its dental effects consistently and independently of any possible help or hindrance from other constituents of drinking water. He has stated, for example, that 1 p.p.m. of fluorine in water will result in dental fluorosis occurring in about 10% of the persons who drink that water whilst their teeth are developing, but with 2 p.p.m. of fluorine the corresponding figure for dental fluorosis will be about 60%. I have seen a little evidence to suggest that there may possibly be exceptions to a rule of this kind, but my own findings in South Shields fitted in very well with Dean's figures.

By the mottled enamel of dental fluorosis I mean paper-white patches which compare with normal enamel very much as the broken edge of a white china saucer compares with the glazed unbroken surface of the saucer. Sometimes these patches are very obvious, but sometimes they are seen only with difficulty and from a particular angle. They may not be easily seen in artificial light. They are produced by interference with the calcification of the enamel and, therefore, they never develop after eruption of the tooth, however great may be the intake of fluorine. During the post-eruptive life of the teeth, these white patches have a tendency to become pigmented, and the higher the fluorine content has been during the development of the teeth and, therefore, the greater the interference with calcification, so the greater will be the tendency for pigmentation to develop. In South Shields I saw

pigmentation in only 2 out of 500 12-year-old children, whereas in Maldon it is very common. The great majority of observers have been able to find mottling and pigmentation in the permanent dentition only, but Marshall Day (1940) has recorded a high incidence of mottling in deciduous teeth in one district in India.

It is, I think, established beyond any doubt that there is no relationship whatever between mottling and freedom from or susceptibility to caries. If one examines in South Shields a sufficiently large number of children showing enamel mottling and compares them with an equal number of South Shields children showing no sign of mottling, the incidence of caries will be found to be precisely the same in the two groups. Similarly, a given number of, say, six-year molars in South Shields showing mottling will be found to show no more and no less caries than the same number of unmottled six-year molars in South Shields—assuming, of course, continuous residence in the area by all the children concerned. This is, I think, a little surprising. It might have been expected that when a substance like fluorine produces two effects on the teeth, namely, mottling and reduction in caries liability, there would be some connexion between the two effects, but apparently there is none whatever.

Those who have subjected mottled teeth to histological examination seem to be agreed that mottled enamel is defective in its structure. Lady Mellanby (1934), for example, said "The prisms are imperfectly calcified, . . . the interprismatic substance is also deficient", whilst McKay (1929) went so far as to say that mottled enamel is "the most poorly constructed enamel of which there is any record in the literature". On the other hand, King (1944), on the basis of clinical examination of Maldon teeth, has recorded his view that, even when mottled, they are often of good structure and his figures make it clear that, in his opinion, the first permanent molars which he saw at Maldon tended to be of better structure than those which he saw in the rural parts of the Island of Lewis.

Fluorine is by no means a rare element, though I was greatly surprised to see it stated in a recent American technical journal that it is about as abundant as nitrogen or carbon. It is coming to be used very widely in industrial processes, and one of the methods employed in separating the isotopes of uranium for the atomic bomb involved the use of a fluorine compound. In this country there seem to be few communities of any size which are dependent on a water supply containing significant amounts of fluorine. Most of the larger cities get their water from moorland gathering grounds, and those waters have little chance of picking up fluorine. Those fluorine-free waters are usually soft, whereas the deep well waters in which fluorine is more likely to be found are often hard. One has, therefore, to meet the argument that the caries-inhibitory effect of waters containing fluorine may be due to hardness and not to fluorine, but I should be sorry to think that there is still any widespread belief that caries incidence is related to hardness or softness of water. In any case, there is convincing evidence from America to show that waters with caries-inhibitory properties vary so widely as regards their hardness and contain salts of all kinds as to rule out the possibility of any ingredient other than fluorine being the caries-inhibiting factor. In a symposium published by the American Association for the Advancement of Science (1946) there is a particularly convincing set of Tables, giving a detailed analysis of the water supplies of 21 towns in the U.S.A., with records of the incidence of caries and of dental fluorosis in those towns.

The fluorine content of articles of diet other than water is, generally speaking, low. An exception is tea leaves, which may contain substantial quantities; the highest of which I have seen a record was almost 1,800 parts per million. Even so, however, the amount of fluorine which one could obtain from tea would be very small. The fluorine content of fish is relatively high; a common value seems to be about 7 parts per million, but presumably a great part of that would be concentrated in the bones which would not, except in the case of the smaller fish, be eaten. The inhabitants of Tristan da Cunha, who seem fated to be quoted in every discussion about dental caries, have practically no fluorine in their drinking water, but their freedom from caries has been attributed to the large part which fish plays in their diet, and which is presumed to supply them with an appreciable amount of fluorine.

Having regard to the fact that marine products tend to have a considerable fluorine content it is rather strange that, so far as I know, no one has ascertained and recorded the fluorine content of cod-liver oil. Is its fluoride content sufficiently high to account for any beneficial effect it may have in inhibiting caries? It may be that the technical problem of estimating fluorine in an oil is a difficult one, but it would be of interest to know what the content in cod-liver oil really is.

The only other constituent of our diet which seems liable to contain any great proportion of fluorine is baking powder. In Nature, fluorides are usually found in association with phosphates, and certain baking powders contain a great deal of phosphate. I understand that those powders have tended to contain so much fluorine that the Society of Public

Analysts felt that it would be desirable to have a statutory limit placed on the fluorine content of baking powder. I am under the impression that the figure they had in mind was 300 parts per million, but presumably the Minister of Health did not think that baking powder constituted a danger to health by reason of being a source of fluorine. At any rate, I have not heard of any statutory upper limit having been fixed.

Judging by the bewildering variations in the recorded fluorine content of bones and teeth, the accurate estimation of fluorine calls for a good deal of experience and skill. I once tabulated all the analyses of bones and teeth which I had been able to find in the literature, and it was clear that a great many of them must have been wrong. Thewlis (1940) gave the fluorine content of human enamel as 0.02%, and this figure corresponds so closely with the figure of 0.025% given by Bowes and Murray a few years earlier that it seems reasonable to regard it as reliable. Incidentally, it is of interest to note that Thewlis gave the fluorine content of dogs' enamel as nil, and yet the teeth of dogs hardly ever develop caries.

There was one analysis carried out in America by Armstrong and Brekhuis (1937), whose figures have been quoted over and over again as proving that the enamel of a carious tooth contains not much more than half the amount of fluorine contained in the enamel of a sound tooth. In view of the fact that their figure for the enamel of a sound tooth was only about half of that recorded by Thewlis and by Bowes and Murray, it seems unwise to quote, as many people have done, the Armstrong-Brekhuis figures as if they had settled once and for all the difference between caries-free and caries-attacked enamel. I feel that a repetition of the Armstrong-Brekhuis analysis is long overdue.

I do not intend to describe in detail my North and South Shields investigation (Weaver, 1944), but just a few of the principal findings. In North Shields water the fluorine concentration was found to be less than 0.25 p.p.m., whilst in South Shields the corresponding figure was 1.4 p.p.m. Five-year-old children in South Shields had in their deciduous teeth only 60% of the amount of caries found in similar children in North Shields—the comparison being made by recording and aggregating all decayed, missing and filled (DMF) deciduous teeth. 12-year-old children in South Shields had, similarly, 56% of the number of DMF permanent teeth found in children in North Shields. It is universally agreed that in fluorine areas the incidence of caries of the upper permanent incisors is particularly low. South Shields proved to be no exception to this rule; it showed DMF upper central permanent incisors to be only 13% of the North Shields figure, whereas for upper first permanent molars the South Shields figure was 64% of that for North Shields.

The low incidence of caries of the upper permanent incisors in fluorine areas has caused some people to put forward a suggestion which seems quite fantastic, viz. that water when taken into the mouth comes first in contact with the anterior teeth, and these teeth adsorb fluorine from the water, leaving it with insufficient to produce the same effect on the posterior teeth. If this were so, presumably upper deciduous incisors in a fluorine area would show a freedom from caries similar to that displayed by the permanent incisors, but they certainly do not. In South Shields the number of DMF deciduous upper central incisors was almost as great as the number of DMF deciduous upper first molars, whereas for the permanent dentition there were found over 50 times as many DMF upper first molars as DMF upper central incisors. The explanation which seems to me best to fit the facts is that a tooth which has little natural tendency to develop caries, such as a permanent incisor, obtains from fluorine that little extra protection which it needs. If, however, it is of a type which is prone to caries, as is an upper deciduous incisor or a molar, fluorine is not a sufficiently powerful inhibitor of caries to protect it in more than a minority of cases.

I think the most important lesson to be learned from the North and South Shields investigation is that the caries-inhibitory property of fluorine seems to be of rather short duration. The incidence of caries in an experimental and a control group is usually shown by recording the number of DMF teeth in each group, and then expressing the number in one group as a percentage of the number in the other group. Using that method, the average number of DMF permanent teeth in 12-year-old children in South Shields was 56% of the average number in North Shields. There is, therefore, some justification for saying that fluorine inhibited caries in South Shields children to such an extent as to reduce the incidence of caries by nearly half—a really remarkable result. I suggest, however, that such a comparison can be most misleading. The 12-year-old children in South Shields averaged 2.4 DMF permanent teeth, whilst the corresponding children in North Shields averaged 4.3 DMF permanent teeth. The question which really needs to be answered is "How many years does it take for the figure of 2.4 in South Shields to reach 4.3?" The answer is approximately three years. It is, of course, true that during those three years the figure of 4.3 in North Shields is also increasing, but the fact remains that at 15 years of age children in South Shields have the same average amount of caries as is found in North Shields at 12 years of age. A further investigation into the dental condition of adults in the two towns showed that in them caries was postponed for about five years. I should like it to be clearly under-

stood, however, that when I refer to fluorine as having the power only to postpone the onset of caries for three to five years, I do not mean that this holds good for each separate tooth or for each separate individual. It is a statement, from the epidemiological angle, of what increase in caries incidence may be expected in a certain group in a certain number of years, but it gives no information whatever as to the increase in caries incidence which may be expected in any individual member of the group. I suggest, however, that when any given regime or procedure is claimed to be of value in reducing the incidence of caries, those whose concern is with the manifestations and effects of dental disease in the community should not be satisfied with the traditional kind of evidence; evidence regarding the duration of the protection rather than that based on percentage comparisons should be asked for.

I might add, in passing, that if the protection given by fluorine in South Shields had not been shown to be of quite brief duration, members of the dental profession would have been faced with an embarrassing question. That question would have been "If the incidence of dental caries in South Shields is so very much less than in North Shields and if dental disease is inimical to health, why is it that there seems to be no evidence that the South Shields population is healthier than the population of North Shields?" The answer, of course, is that the figure of 56% which I have given in connexion with the findings for 12-year-old children is misleading; that there is in fact no very striking difference in the incidence of caries in the two towns, and therefore that there is no reason to expect South Shields to have a better health record than North Shields.

Having indicated that only a limited beneficial effect can be expected from the ingestion of fluorine in drinking water, something needs to be said about the possibility of its doing any harm. A good deal has been written, notably by Roholm (1937), about the toxicology of fluorine, but he was concerned mainly with effects produced by the quite exceptional conditions experienced by workers in cryolite—a fluorine compound obtained in Greenland and refined in Denmark. There have been reports from India of severe skeletal disabilities, apparently resulting from the ingestion of fluorine, but the water supplies invariably contained unusually high concentrations of fluorine—far beyond anything which is found in this country. There has been a small-scale investigation in England by Kemp, Murray and Wilson (1942), in the course of which radiographs were taken of a number of spines with a view to discovering whether spondylitis deformans might be related to fluorine intake. The investigators concluded that spondylitis deformans was fairly common, whether or not there was evidence of dental fluorosis. They added that fluorine in soil and water, in association with defective nutrition, may favour such maldevelopment; they did not, however, seem satisfied that it often does so.

McClure (1944) found no relationship between fluoride exposure and fracture incidence. He considered that his findings pointed to the unlikelihood of skeletal development being adversely affected by continued ingestion of drinking water containing up to 6 p.p.m. of fluorine.

It is claimed by Dagmar Wilson (1941) that fluorine areas show an unusually high incidence of goitre, but I did not find goitre to be prevalent in north-east Durham. If the intake of fluorine is very high, it is possible that damage to the kidneys may result, and there have been statements to the effect that fluorine considerably lengthens the clotting time of the blood, though this has been disputed. Fluorine is a very toxic substance, and if ingested in large quantities it will do considerable harm, but the evidence which I have seen has given me no reason to think that, apart from the rather unsightly appearance of the teeth in some areas, there would be any harmful effect produced by the long-continued ingestion of any fluorine-containing water found in this country.

Does fluorine produce its caries-inhibitory effect during the pre-eruptive or the post-eruptive life of the teeth? If it were produced during pre-eruptive life, presumably it could only be by way of effecting some modification in the structure of the teeth, making them more resistant to attack. One thinks, for example, of the way in which the addition of very small amounts of other substances affects the properties of steel, producing stainless steel with its high power of resistance to corrosion, which is a chemical attack, and one wonders whether the incorporation in the developing enamel of quite small amounts of fluorine so alters its chemical constitution as to render the enamel more resistant to chemical attack. Laboratory experiments have been carried out in which powdered enamel has been treated with various fluorides, and an apparent reduction in enamel solubility has thereby been secured. It is, however, doubtful whether conclusions from these *in vitro* experiments are valid for teeth in the mouth; it seemed, for example, as if lead fluoride was particularly effective in the laboratory in reducing enamel solubility, and yet topical application of lead fluoride solution to teeth in the mouth appeared, according to one investigation, to produce no beneficial effect.

An effect produced by fluorine during the post-eruptive life of the teeth might result either from an increase in their resisting power or from a change in their environment—in

other words, it could either strengthen the defence or weaken the attack. I, therefore, examined 800 children who had been born outside the north-east Durham area and had come to live in it at various ages. It was only the six-year molars which were curious in numbers sufficient to provide any evidence of value, and, so far as caries of those teeth was concerned, it seemed to be established that, up to and including the age of about 5 years, it did not matter whether the child's residence in the fluorine area had been long or short. To put it in another way, children who came to live in the fluorine area appeared to have an average caries incidence in their six-year molars which was quite independent of the age at which they arrived there, provided—and this is important—provided they got there before the age of 6. Now this seemed to indicate that, in order to obtain protection for the six-year molars, it was not essential that the child should have been ingesting fluorine for a considerable time; what did seem to be essential for maximum protection was that the child should have ingested fluorine for a period, though probably only for quite a brief period, before the eruption of the six-year molars. However, children arriving in the fluorine area at 6 years of age appeared to derive some benefit, whilst those arriving at 7 years of age or later apparently derived no benefit at all so far as protection of their six-year molars was concerned. It seemed, therefore, that if fluorine confers on the tooth any protection during its post-eruptive life, it is only during a quite brief period following eruption that such protection can be acquired. This is not easy to accept, though in correspondence which I have had with Bibby, he has put forward an ingenious theory to account for it. Briefly, it is this. Newly erupted enamel is prepared to adsorb a number of different substances from its environment. If that environment contains fluorine, the enamel will adsorb fluorine; if the environment does not contain fluorine the enamel will adsorb another substance or substances which will, so to speak, exhaust its adsorptive capacity and so render it incapable of taking up fluorine even if it gets the chance to do so later on.

Therefore, the examination of those 800 children did not provide a perfectly definite answer to the question of pre-eruptive *versus* post-eruptive influence. It appeared to me probable, on the basis of my findings, that the protection was acquired during a late stage in the pre-eruptive life of the tooth, but I could not rule out the possibility that it might be acquired just after eruption. At first I thought that the uncertainty was due to the fact that 800 children did not constitute a sufficiently large number when divided into age-groups, but I am now satisfied that the same uncertainty would have followed an examination of ten times that number of children, if it had been possible to find such a number fulfilling the necessary conditions. The uncertainty is really due to the fact that, although it was possible for me to get precise information about the time of a child's arrival in the fluorine area, I could not say, in the case of a child who had arrived there somewhere about the age of 6 years, which, if any, of its six-year molars had erupted before its arrival. There seems no way of overcoming this difficulty in any investigation of the type which I carried out but it can, and I expect will, be overcome by utilizing the data from those American communities where fluorine is now being added to the water supplies. If, immediately before the commencement of the addition of fluorine, children have been dentally examined and a record has been made of which teeth have erupted and which have not, then it will be possible to compare in due course the caries incidence of those teeth which were erupted before the addition of fluorine with the incidence in those which were unerupted.

There have been in America several investigations based on the same idea as the one I carried out. Some of them have been done in areas where there was a change in the fluorine concentration in the water supply—sometimes from high to low fluorine content, and sometimes from low to high fluorine. Others have been concerned with persons whose place of residence had changed. None of them, however, has seemed to me to provide convincing results; indeed, the conclusions of different observers have given rise in my mind only to confusion.

A certain amount of work has been done with a view to finding out whether fluorine produces any significant change in the environment of the teeth. There seems to be general agreement that the activity of salivary amylase is not affected by fluorine even in quite high concentrations. Children drinking water containing 1.8 p.p.m. of fluorine were recorded by McClure (1939) as having just the same salivary amylolytic activity as children drinking fluorine-free water. *Lactobacillus acidophilus* counts have not always given consistent results but, on the whole, children drinking water containing significant quantities of fluorine tend to show considerably lower *Lactobacillus* counts than do those using fluorine-free water. Whilst, however, many people accept it as established that there is an association between high *Lactobacillus* counts and high caries activity, it is by no means accepted that this relationship is one of cause and effect—or rather, one might say it is not certain which is cause and which is effect.

With a view to reducing the caries incidence in areas where there is little or no fluorine in the drinking water, four methods of utilizing the caries-inhibitory property of fluorine

have been suggested. They are: (1) Addition of fluoride to drinking water; (2) administration of fluoride in solid form; (3) topical application of fluoride solution to the teeth; (4) incorporation of fluoride in dentifrices.

Let us consider first the addition of fluoride to drinking water. At the present time there are eight communities in the U.S.A. and Canada where fluorine is being added to the domestic water supply for the purpose of studying the effect on dental caries. The first of these community experiments was begun at Grand Rapids, Michigan, in January 1945, and a preliminary analysis of the dental findings so far has been made but, as yet, nothing has to my knowledge been published. The fluorination of water does not appear to present any technical difficulty, and the cost is not high. One American estimate of the expenditure is that it would amount to about 7½ cents per head of the population per annum.

In spite of the ease and cheapness of this method it is not, however, one to be adopted without very serious consideration. There are many people who would object strongly to what they would regard as tampering with their water supply, and public opinion in a matter of this kind cannot safely be ignored. I have heard of one American community where there had been some publicity about a proposal to fluorinate the local water supply, and some time later the Public Health Department began to receive complaints from residents that since the addition of fluorine to the water their teeth had gone to the dogs. In fact, the project had never got beyond the stage of talking about it, and no fluorine had ever been added.

It has not, so far as I know, ever been suggested that a community water supply should have its fluorine content raised to a level above 1 p.p.m. That being so, I think there is no reason to anticipate that the addition would do any harm, but mention should be made of other objections to the procedure.

The first is that it is regarded, not unnaturally, by many water engineers as a clumsy method. To add fluoride to the whole of a town's water supply in order to fluorinate the comparatively small proportion of that supply which is actually drunk seems to them uneconomical. If it is argued that the whole of a town's water supply has to be chlorinated in order that the inhabitants may drink chlorinated water and thereby obtain protection against water-borne diseases like typhoid fever, a further objection would be that the protection afforded by chlorination is enjoyed by the whole community. On the other hand, it may well be that fluorination would not benefit in the least the residents whose teeth would have been already formed at the time fluorination was commenced, and even in the case of children whose teeth would be exposed to fluorine during the whole period of their development, there would be quite a number who would apparently derive no benefit. To illustrate this point, I might mention that the first four children whom I examined in South Shields had between them 41 DMF teeth. It could be argued that, if they had not been ingesting fluorine the number of their DMF teeth would have been much more than 41, but it must be admitted that if those four children had derived any benefit from fluorine, the benefit was by no means obvious.

Next, it might be claimed that "doctoring" of the water supply would be justified if it could be established that some permanent or long-continued reduction of caries could be achieved, but that it is not justified if the reduction of caries is merely a transient effect—a delaying action rather than a prevention of caries.

Finally, it would be argued that the amount of fluorine ingested from water depends not only on the concentration of fluoride in the water, but also on the quantity of water which is drunk. In this respect there are substantial differences between different individuals and also, in the same individual, there may be differences depending on the season of the year. In order to ensure a uniform intake of fluorine from water for the whole year it might be necessary to vary the content between say 0·7 p.p.m. at the height of summer and perhaps twice that concentration in the depth of winter. A complication is thus introduced, and objections would doubtless be made to the content ever being raised above 1 p.p.m.

We turn now to the second method, namely, the administration of fluoride in solid form. There are precedents for a procedure of this type, notably the iodizing of salt for the prevention of goitre, and the addition of calcium to flour. Some enthusiastic advocates of water fluorination claim that the beneficial effect of drinking water which contains fluorine is the result of the fluorine being adsorbed by the teeth during its passage through the mouth, rather than from any effect produced by the fluorine after it is swallowed. They would accordingly argue that fluoride passing through the mouth in solid form could not readily be adsorbed by the teeth and would, therefore, be comparatively ineffective. It seems to me, however, that the evidence for their argument is very thin and, I think, therefore, that the ingestion of fluoride in solid form by those who want it is much to be preferred to the compulsory ingestion of fluorine in water both by those who would welcome, and those who would strongly object to, such a procedure. Incidentally, those who wish to take fluorine could take it either in solid form or as an addition to the household water, but it is probable

other words, it could either strengthen the defence or weaken the attack. I, therefore, examined 800 children who had been born outside the north-east Durham area and had come to live in it at various ages. It was only the six-year molars which were carious in numbers sufficient to provide any evidence of value, and, so far as caries of those teeth was concerned, it seemed to be established that, up to and including the age of about 5 years, it did not matter whether the child's residence in the fluorine area had been long or short. To put it in another way, children who came to live in the fluorine area appeared to have an average caries incidence in their six-year molars which was quite independent of the age at which they arrived there, provided—and this is important—provided they got there before the age of 6. Now this seemed to indicate that, in order to obtain protection for the six-year molars, it was not essential that the child should have been ingesting fluorine for a considerable time; what did seem to be essential for maximum protection was that the child should have ingested fluorine for a period, though probably only for quite a brief period, before the eruption of the six-year molars. However, children arriving in the fluorine area at 6 years of age appeared to derive some benefit, whilst those arriving at 7 years of age or later apparently derived no benefit at all so far as protection of their six-year molars was concerned. It seemed, therefore, that if fluorine confers on the tooth any protection during its post-eruptive life, it is only during a quite brief period following eruption that such protection can be acquired. This is not easy to accept, though in correspondence which I have had with Bibby, he has put forward an ingenious theory to account for it. Briefly, it is this. Newly erupted enamel is prepared to adsorb a number of different substances from its environment. If that environment contains fluorine, the enamel will adsorb fluorine; if the environment does not contain fluorine the enamel will adsorb another substance or substances which will, so to speak, exhaust its adsorptive capacity and so render it incapable of taking up fluorine even if it gets the chance to do so later on.

Therefore, the examination of those 800 children did not provide a perfectly definite answer to the question of pre-eruptive *versus* post-eruptive influence. It appeared to me probable, on the basis of my findings, that the protection was acquired during a late stage in the pre-eruptive life of the tooth, but I could not rule out the possibility that it might be acquired just after eruption. At first I thought that the uncertainty was due to the fact that 800 children did not constitute a sufficiently large number when divided into age-groups, but I am now satisfied that the same uncertainty would have followed an examination of ten times that number of children, if it had been possible to find such a number fulfilling the necessary conditions. The uncertainty is really due to the fact that, although it was possible for me to get precise information about the time of a child's arrival in the fluorine area, I could not say, in the case of a child who had arrived there somewhere about the age of 6 years, which, if any, of its six-year molars had erupted before its arrival. There seems no way of overcoming this difficulty in any investigation of the type which I carried out but it can, and I expect will, be overcome by utilizing the data from those American communities where fluorine is now being added to the water supplies. If, immediately before the commencement of the addition of fluorine, children have been dentally examined and a record has been made of which teeth have erupted and which have not, then it will be possible to compare in due course the caries incidence of those teeth which were erupted before the addition of fluorine with the incidence in those which were unerupted.

There have been in America several investigations based on the same idea as the one I carried out. Some of them have been done in areas where there was a change in the fluorine concentration in the water supply—sometimes from high to low fluorine content, and sometimes from low to high fluorine. Others have been concerned with persons whose place of residence had changed. None of them, however, has seemed to me to provide convincing results; indeed, the conclusions of different observers have given rise in my mind only to confusion.

A certain amount of work has been done with a view to finding out whether fluorine produces any significant change in the environment of the teeth. There seems to be general agreement that the activity of salivary amylase is not affected by fluorine even in quite high concentrations. Children drinking water containing 1.8 p.p.m. of fluorine were recorded by McClure (1939) as having just the same salivary amylolytic activity as children drinking fluorine-free water. *Lactobacillus acidophilus* counts have not always given consistent results but, on the whole, children drinking water containing significant quantities of fluorine tend to show considerably lower *Lactobacillus* counts than do those using fluorine-free water. Whilst, however, many people accept it as established that there is an association between high *Lactobacillus* counts and high caries activity, it is by no means accepted that this relationship is one of cause and effect—or rather, one might say it is not certain which is cause and which is effect.

Electromyography

By P. BAUWENS

Director of the Department of Physical Medicine, St. Thomas's Hospital, London

A MORE scientific approach to the study of electric changes in contracting muscle became possible with the advent of Lippmann's capillary electrometer (invented 1875) and later Einthoven's string galvanometer (invented 1906). The moving parts of these instruments were sufficiently light to follow the rapid variations of potential. They moreover allowed records to be made so that analysis of both wave-form and frequency became possible.

Limited though these instruments were, they served their masters well, and enabled Piper and more recently Adrian, Bronk and Matthews to lay the foundation on which clinical electromyography must forever rest.

Recent investigators in the field of electrical activity in muscles and nerves have enjoyed the great advantage derived from the development of valve amplifiers. Well-designed equipment of this type can magnify fluctuating potentials applied to it as much as a million times without appreciable distortion of wave-form. Once the potentials have attained a sufficient magnitude they can be measured with appropriate instruments; translated into sound in a loud speaker; projected as visible waves on to the screen of a cathode-ray oscilloscope and permanently recorded on gramophone discs or photographic films, or again—within certain limits of frequency—on paper by means of electromagnetic pen recorders.

The equipment recently constructed by Peter Styles at St. Thomas's Hospital has two completely separate channels each with its own amplifying, measuring, monitoring, calibrating and recording devices (fig. 1). It also incorporates an electrical stimulator which is synchronized with the sweep of both monitoring cathode-ray oscilloscopes.

From its history it is obvious that electromyography as it is known to-day is a direct application of electrophysiology to clinical medicine.

The intimate mechanism of production of biological electricity has for many decades attracted the attention of biophysicists and many are the hypotheses which

that the latter method, involving the making-up of a solution of given strength, would be much the less popular. The fluorine to be taken in the solid form might well be incorporated in tablets of prescribed composition, containing say 1 mg. of fluorine as fluoride, for use in an area with a fluorine-free water. If the water contained some fluorine, the tablets should contain proportionately less. It has been suggested that bone meal would serve as a source of fluorine to be taken in solid form, but analyses of bone meal show considerable variations in fluorine content, and so this method of giving fluorine is rather lacking in precision.

The topical application of fluorine, that is, the painting of the teeth with a fluoride solution, has been carried out on a considerable scale in America. In this country an investigation has been carried out at a residential school in Cheshire by Professor Stones of Liverpool, assisted by members of his staff at the Dental Hospital. The experiment itself was completed some considerable time ago, but there has been a delay in obtaining a statistical analysis of the results. Although many of the reports from America are most enthusiastic about this procedure, I should prefer to suspend judgment as to its value until Professor Stones' figures are available. One American investigation by Arnold, Dean and Singleton (1944), carried out in the U.S. Coast Guard Academy, led the investigators to conclude that 'there is no evidence in this study that a single topical application of a fluoride solution to the teeth of young adults as here carried out would result in reduction of dental caries incidence'.

On the other hand, there are numerous American reports of striking effects having been produced in children by multiple applications of a 2% sodium fluoride solution. A typical report is that by Galagan and Knutson (1947) a few months ago, in which they record having applied sodium fluoride solution to the teeth on one side of the mouth of 1,555 children—the teeth on the untreated side acting as controls. They state that the incidence of initial caries in permanent teeth which were non-carious at the time of treatment with 2, 4 and 6 applications was, after an interval of a year, 21·7, 40·7 and 41% less respectively in treated than in untreated teeth. They believe that four topical applications of sodium fluoride, preceded by dental prophylaxis, afford maximum reduction in dental caries incidence.

One of the reasons for hesitation in accepting unreservedly the claims for the value of topically applied sodium fluoride is the fact that the results of its application to mandibular teeth have been usually much less beneficial than in the case of teeth in the upper jaw. Various attempts have been made to explain why this should have happened, but the explanations do not seem to be entirely convincing.

As for the addition of fluoride to dentifrices, it was suggested in an editorial article in the *British Medical Journal* that the time might come when legislation should provide for the compulsory inclusion of specified amounts of fluorine in every dentifrice sold to the public. I know of only one experiment designed to test the value of fluorine used in this way; it was carried out by Bibby (1945). Both a liquid and a paste dentifrice were supplied, sodium fluoride being incorporated either in 0·01% or 0·1% strength. The users were dental students and orphanage children. Bibby reported that no evidence of a reduction of caries activity was found—a result which did not surprise him so far as the young adults were concerned, but which was quite contrary to his expectations regarding the children. I have heard recently of one British firm contemplating the manufacture of a fluoride-containing toothpaste, but up to the present I have seen no evidence which would justify encouragement of such a venture.

responses of these muscle fibres are simultaneous, the electrical disturbance caused by the excitation of a motor unit is substantially a large amplitude diphasic wave which after amplification evokes a popping noise from a loud speaker.

Even the weakest possible voluntary movement of a muscle appears to entail the excitation of several motor units but the activity of these under normal conditions is not synchronized. On the contrary, Nature seems to have been at pains to ensure that they not only fire out of step but also that adjacent ones have different firing frequencies. All the same, there is some evidence that during maximal exertion a certain rhythm somewhat resembling a beat frequency develops. Piper, who first described this phenomenon in man, insisted that the basic frequency approached 50 per second.

When the clinic replaces the laboratory, and the patient the experimental animal, the method of leading off these potentials has to be modified, and surface electrodes or needle electrodes are employed. The former record, at the level of the skin, the integrated potentials caused by the electrical disturbances in a large and ill-defined muscle mass in the field between the two electrodes which may be several inches apart. This method is useful for cursory examinations and where collective effects are investigated. Its lack of accuracy and the fact that some electrical fluctuations of short duration cannot be picked up by this method, make the second method the one of choice. Here the two electrodes are concentrically disposed. Such an arrangement is conveniently obtained by fitting an insulated metal shaft into the lumen of an ordinary syringe needle. It is important to realize that with this method one obtains samples of electrical disturbances in a very restricted volume of the tissues but that these can be localized with great precision.

When making electromyographic observations it is important to bear in mind the structures involved. These are diagrammatically illustrated in fig. 2. Two motor units are represented, MU¹ and MU², with the nerve fibres supplying them: NF¹ and NF² respectively.

Under resting conditions in a normal subject, no electrical activity is detected either by means of the surface electrodes (SE) applied to the skin or the needle electrodes (NE) inserted into motor unit (MU¹).

Were motor unit 1 to enter into activity as the result of volition, then all the muscle fibres in this unit would contract simultaneously. Each would supply its own contribution of electrical potential and as a result a popping sound would issue from the loud speaker (LS) while a discrete diphasic wave (fig. 3) would be produced on the screen of the cathode-ray oscilloscope (CRO) and on the paper of the pen recorder (PR). Increased exertion would first cause an increase in the repetition frequency of this diphasic discharge and then bring other motor units into play. It is interesting to note that supposing motor unit 2 (MU²) became active, the discharges from this would not be synchronized with those of motor unit 1 (MU¹) and would probably have a different frequency.

The asynchronous activity of motor units when integrated expresses itself as an interference pattern on the screen of the CRO and on a penned record (fig. 4) and an irregular rumble in the loud speaker.

Synchronized activity in motor units occurs as the result of tendon reflexes (fig. 5), electrical stimulation of nerve trunks and, as will be seen later, under some pathological conditions.

On maximal exertion both the wave graph and the sound are sustained. Failure to obtain this is highly suspicious of inactivity on the part of a large proportion of motor units.

have emerged from their labours. If the theoretical considerations concerning the nature of action potentials are purely academic, a knowledge of their possible origin and the factors which may evoke them has none the less a practical value.

It has long been recognized that most vital processes, if not electrical by nature, are often inseparably associated with electrical phenomena. In common with other living systems, excitable tissues are electrically polarized. This means that on either side of a limiting surface which appears to keep them apart there exist positive and negative charges.

Nerve and muscle fibres share the distinction of being polarized in this manner—negatively at the centre and positively on the outside. That these potential differences exist can easily be shown by means of a sensitive galvanometer connected across the raw and the uninjured surfaces of a recently cut muscle.

During activity these charges appear to neutralize one another, as if the insulating properties of the structure separating them had broken down. The sudden disap-

pearance of the localized charges invariably results in a readjustment of electrical balance in the surrounding structures which virtually constitute an external circuit. The disturbances thus produced are the very ones with which we are concerned.

In the physiological laboratory, where precision experimentation can be carried out by dissection and the use of conditioning drugs, it is possible to demonstrate that local activity in a single nerve or muscle fibre is accompanied by a rapid variation of electrical potential. Since the zone of activity is propagated along the fibre, it follows that the associated electrical by-products will similarly move along. When the electrical phenomena are recorded by means of two electrodes in contact with the fibre, the influence of the propagated electrical potential on each one in turn produces the typical diphasic wave which has come to be called spike potential.

Again, in the laboratory the simultaneous stimulation of two or more fibres is feasible. In the case of muscle the integrated electrical effects of several fibres manifest themselves—with certain reservations—by an increase in the amplitude of the resulting diphasic wave. In the intact animal, however, the smallest unit which normally enters into activity as the result of volition is not a single muscle fibre but a group embodying as many as 300 or more fibres supplied by one motor nerve fibre. As the

of great diagnostic and prognostic significance in peripheral nerve injuries. They are of assistance in differentiating quantitatively between complete and partial denervation and qualitatively between paralysis due to transient nerve block and that due to axon degeneration.

In the presence of normal motor unit activity on volition and either silence or fibrillation potentials at rest, the electromyographic interpretations are moderately simple. Unfortunately a whole gamut of other electrical disturbances of less easily recognizable origin can come to light. They may occur spontaneously or be provoked by manipulation or movement of needle electrodes.

The spontaneous ones may range from the fibrillation potentials, already discussed, to intermittent trains of oscillations of high frequency. In between these two extremes there are discrete, high amplitude discharges of either a diphasic or highly complex

FIG. 4.—Electrical activity in a normal muscle with increasing exertion.

type. Again, they may come at random, rhythmically or in surges. Many of them can be evoked by movements of a needle electrode, attesting to their peripheral origin.

At times the frequency is sufficiently high to give rise in the loud speaker to a quasi-musical sound.

A medley of these may occur in motor neurone diseases, as if progressive destruction of a neurone led to a state of irritability at the myoneural junction of which fasciculation is a clinical expression.

The repetitive character of both the fasciculation potentials and the fibrillation potentials suggests some relationship. Fasciculation might possibly be a kind of synchronized fibrillation occurring at a time when the terminal arborization of the diseased nerve fibre is still apt to transmit impulses from one myoneural junction to another.

By referring to fig. 2 and supposing the two motor units depicted to be at different stages of progressive destruction we can in a somewhat over-simplified manner envisage the electromyographic picture to which this would give rise.

At first, motor unit 1 might be diseased and, before complete denervation, might give rise to fasciculation. At that time intact motor unit 2 could still produce normal action potentials on volition. At a later date, while motor unit 2 goes through the fasciculating phase, motor unit 1 might have reached denervation and the individual muscle fibres composing it might produce typical fibrillation potentials. This would give rise to both phenomena at the same time.

The picture becomes even more complicated when the cause of the progressive neurone destruction acts as an irritative process either in part or at one stage. Referring again to fig. 2, suppose a zone of compression at X. This might cause irritation of MU¹ and the setting up of a trigger zone of the type described by Kugelberg, possibly coupled with a simple nerve block above it. This might cause spontaneous discharges in the muscular part of the unit as well as an occasional burst of action potentials on

After section of a nerve fibre the muscle fibres supplied by it naturally lose their power of contracting on volition as well as the collective electrical disturbances associated with this. It does not, however, spell the end of activity of the individual

FIG. 2.—Anatomical structures and electrical equipment involved in electromyographic investigation diagrammatically represented. SC: Lateral view of section of spinal cord. MU¹ and MU²: Two motor units. NF¹ and NF²: Nerve fibres respectively supplying MU¹ and MU². SE: Surface electrodes. NE: Needle electrodes. Amp: Amplifier with output meter. LS: Loud speaker. CRO: Cathode-ray oscilloscope. GR: Gramophone disc recorder. PR: Electromagnetic pen recorder. X: Site of lesion.

muscle fibres composing the motor unit. After a lapse of approximately three weeks these fibres may begin to enjoy an autonomous life of which one manifestation is a rhythmic activity termed "fibrillation". This gives rise to repetitive potentials of short duration and small amplitude which impart a ticking quality to the loud speaker and assume the shape of small spikes on the screen of the cathode-ray oscilloscope. These characteristics make fibrillation potentials easily distinguishable from normal motor unit activity.

FIG. 3.—Three discrete biphasic potentials in normal muscle resulting from electrical stimulation of nerve.

FIG. 5.—Electrical activity in quadriceps muscle as a result of tendon-jerk.

The numerical reduction in normal action potentials on maximal exertion or their total absence, coupled with the presence or absence of fibrillation potentials, can be

experience we have been able to confirm this in advanced cases of progressive muscular atrophy, and anterior poliomyelitis, not only when using two needle electrodes in the same muscle but also when using four surface electrodes on the skin overlying a muscle.

Fig. 8 shows two tracings taken simultaneously from two pairs of surface electrodes disposed on the sole of the foot of a patient suffering from progressive muscular atrophy. The synchronized action of the intact motor units can be deduced not only from the timing of the diphasic waves but also from the high amplitude of the individual discharges.

Buchthal and Clemmessen also draw attention to an interesting phenomenon in this connexion. On fatigue, the motor units drop out one by one thus producing a

FIG. 7.—Electrical activity at rest provoked by manipulation of the neck in a case of suspected disc lesion.

decrease both in amplitude of the individual diphasic waves, but also in the frequency.

It is possible that better acquaintance with these phenomena may eventually assist in the early differential diagnosis of simple polyneuritis and motor neurone diseases.

In myopathies where the muscular weakness results from a diminution in the number of effective muscle fibres rather than from a numerical reduction in whole motor units, a decrease in the amplitude of the spikes can be expected. As Kugelberg points out, in myopathies the emphasis is on spikes with narrow bases and of small amplitude but—except in advanced cases—of frequencies approaching that encountered in normal muscles.

The few congenital amyotonias I have had the opportunity of examining have revealed the existence of sustained electrical activity simultaneously in antagonistic groups of muscles even though these appeared flaccid.

Buchthal and Clemmessen have studied the electrical activity at rest in some of the

FIG. 8.—Simultaneous tracings showing synchronized activity throughout the plantar muscles demonstrated by the use of two independent pairs of electrodes applied to the sole of the foot during attempt at flexion of toes in a case of advanced progressive muscular atrophy.

painful conditions in muscles, associated with palpable alterations in the consistency of the muscles. It would appear that this activity can be abolished by injection of a

volition when the block is jumped—as may happen intermittently (Hodgkin's extrinsic potential).

An even more complex set of conditions worthy of some attention might be set up at the level of a lesion of both irritative and destructive nature. It is now generally accepted that the spike potential in one nerve fibre can stimulate an adjacent fibre provided the threshold of excitability of the receptor fibre is sufficiently lowered.

Recently Granit, Leskell and Skoglund devised ingenious experiments which enabled them to demonstrate that this cross interaction occurred not only at the cut end of nerves but also as the result of pressure or crushing. The practical significance of their results did not escape these workers. They concluded that "an injured or compressed region forms a critical point at which impulses can be reflected centrifugally or centripetally by engaging other fibres by interaction".

Referring once more to fig. 2, it means that compression or injury, say at point X, might cause impulses conducted from the cord in nerve fibre 1 to stimulate nerve fibre 2. The net result would be activity of both motor units which would not be perfectly synchronized on account of the delay at the artificial synapse. Hyperventilation with the consequent lowering of the threshold of excitability would increase the effect.

Arvanikati, while studying "ephapses" as she calls these artificial synapses, found that under certain conditions her cut nerve preparation became the seat of oscillating potentials.

In practice it is found that a prolapsed disc or a constricting lesion produces electrical activity at rest in the muscles supplied by the root or trunks affected by the pressure (fig. 6). The problem here is, should the patient be examined during the acute or chronic

FIG. 6.—Simultaneous tracings of electrical activity in R. and L. biceps showing spontaneous activity in R. biceps presumed to be due to an intervertebral disc prolapse.

stage of the condition and how should one obtain general relaxation of the muscles while lowering the threshold of excitability at the level of the lesion? It may some day prove possible to send antidromic volleys up one nerve and demonstrate, in the presence of a lesion, an electromyographic echo in a muscle supplied by other nerve fibres.

At present it is sometimes possible to record an increase in the activity at rest when an appropriate portion of the spine is manipulated so as to increase the pressure in the case of disc lesions, or the shoulder girdle in the case of upper thoracic outlet syndromes (fig. 7).

Affections of the cord also appear to have their own characteristics. Buchthal and Clemmessen find that in muscle wasting and paresis of cord origin there is a tendency to synchronization of activity in motor units which are still intact. In our limited

[December 18, 1947]

Rheumatic Nodules: Granuloma Annulare.—R. E. BOWERS, M.B.

Mrs. R. S., aged 25.

In 1943 a subcutaneous swelling appeared just below the left olecranon process. Shortly afterwards a similar tumour appeared at the same site on the opposite side.

The patient had been healthy until January 1939, when she was admitted to St. Giles' Hospital with acute bilateral salpingo-oophoritis, a left-sided pyosalpinx and a pelvic abscess. No gonococci found. She was treated conservatively and discharged in March 1939. In 1943 she began to develop rheumatism in the feet, and subsequently in the joints. About the same time the tumours appeared on the forearms.

When first seen at St. Thomas's Hospital in October 1945 she had two lobulated firm subcutaneous swellings in the positions described, freely mobile under the skin and just movable over the bone. Section of the tumour on the left side showed principally masses of endothelial cells and an area of necrosis surrounded by endothelial cells arranged in palisade fashion. The histological appearances suggested granuloma annulare and this was confirmed by Dr. Freudenthal.

The patient was next seen in September 1947, when she also had a small flat plaque on the right foot which clinically suggested granuloma annulare. One of the main lesions was excised.

The W.R. and gonococcal complement fixation tests are negative.

Histology.—(1) *Specimen taken in 1945:* A small area of necrosis with endothelial cells in palisade arrangement at the periphery. Elsewhere masses of endothelial cells without necrosis, and much young connective tissue. In the endothelial masses many new blood vessels. (2) *Tumour excised in September 1947:* Similar to the above except that the areas of necrosis are many and large, and the whole process is accompanied by extensive fibrosis.

Comments.—Large nodules of this type occur in chronic rheumatoid arthritis. In their early stages they show much endothelial proliferation and new vessel formation, but later there appear centres of necrosis surrounded by endothelial cells in a palisade arrangement. Fibrous tissue is laid down round these foci, which eventually may undergo cystic degeneration.

At the stage of necrosis the histological picture may be indistinguishable from that of well-developed granuloma annulare. Dr. Parkes Weber in "Rare Diseases" (1947) quotes Freudenthal as saying that this is so. Dr. A. J. Rook has recently drawn my attention to H. Keil's article (*Medicine*, 1938, 17, 261) in which this resemblance is mentioned, and Dr. Freudenthal has pointed out another reference to it, i.e. H. Jaeger (1946) *Dermatologica*, 92, 325.

In the present case the diagnosis of chronic rheumatic nodules would seem more likely than granuloma annulare. The object in presenting it is to emphasize the histological similarity of the two conditions, and even a certain clinical resemblance. Is it possible that they are related in some way?

Dr. F. Parkes Weber: The histology of the large elbow nodule is certainly that of the typical necrobiotic nodules of rheumatoid arthritis, and, in fact, the patient's fingers resemble those of not very active and not far advanced rheumatoid arthritis.

Dr. G. B. Dowling: About six weeks ago a doctor of 57 saw me for a ringed lesion over two knuckles on the right hand. This he had diagnosed himself as granuloma annulare, but, oddly enough, he did not connect the ringed lesion on the hand with a far more striking lesion on the left elbow. This, a firm subcutaneous tumour-like swelling, began to develop over the posterior border of the left ulna a little below the elbow about two years ago; shortly afterwards a plaque appeared on the back of the right hand which spread, gradually becoming ringed.

He had sciatica three years ago followed later by swelling of fingers and pain in the lower back muscles. Mild degree of pain in muscles and joints persisted.

He exhibited on the back of the right hand a ringed nodular lesion centred by the knuckles of the first and second fingers; on the extensor aspect of the left forearm about an inch below the elbow a subcutaneous tumour-like lesion, freely movable under the skin and over the underlying bone. It felt like a lobulated mass of small firm tumours. Slight swelling of one or two finger-joints was present.

The case is similar in every respect to that presented by Dr. Bowers except that there is one lesion less and the patient shows less rheumatic change.

I was personally unaware that any histological similarity between granuloma annulare and the rheumatic nodule was known to exist. However, Dr. Bowers pointed out to me that this was so, and it was brought home to me again by Dr. Haber in connexion with a third case of the same kind

0.5% novocain solution which interrupts afferent paths without interfering with the motor paths.

Upstream of the anterior horn cells, pyramidal and cerebral affections as well as proprioceptive impulses from collateral afferent paths can mediate the responses of the anterior horn cells or elicit reflex action, so that electrical activity coupled with clinical rigidity may result. In affections of the basal ganglia—such as Parkinsonism—rhythmic surges can be obtained.

I do not anticipate that E.M.G. will for some time to come be used in the same way as radiography, electrocardiography or electro-encephalography, where an operator carries out the technical aspect of the investigation and submits a record for interpretation to a clinician.

It is, in the case of E.M.G., too important to observe the patient personally during the actual examination and, if necessary, to modify the conditions under which the examination is conducted.

It may well be possible in future to standardize recording technique and terminology to such an extent as to make this practicable but the time has not yet come.

I feel that this clinical application of electrophysiology has great potentialities but that the value of the contribution which it may ultimately bring to neurology will in a large measure depend on how well it is supported during its developmental stages by the tripod made of the neurologist, the neurosurgeon and the morbid pathologist.

Each of these can confirm or reject a tentative diagnosis either on clinical grounds or as the result of an exploration or a biopsy.

Dr. Graham Weddell was the pioneer worker in this field. In collaboration with Feinstein and Pattle he investigated a number of conditions presenting interesting electromyographic features. By overcoming some of the technical difficulties which had prevented electromyography from emerging from the laboratory they put it at the disposal of the clinician.

I also wish to pay a tribute to Mr. Peter Styles whose ability has made further technical developments clinically accessible.

Dr. Graham Weddell said that electromyography was not only a valuable aid to diagnosis but was of importance also in relation to the physiology of muscular contraction. Dr. Weddell stated that he and his colleagues were particularly interested in the total pattern of innervation of a voluntary muscle and were planning to correlate anatomical findings with the results of action potential recordings. In his department Dr. W. H. Feindel had developed a new staining technique using methylene-blue, by means of which it is possible to study the innervation of an entire muscle without the distortion consequent upon local injection of the dye. It was proving of extreme value in this connexion. Dr. Weddell showed a number of slides illustrating some of the details of the pattern of innervation of muscle upon which he and his colleagues were at present engaged. He pointed out the value of making electromyographical studies in disease processes involving the muscular and nervous systems, as Dr. Bauwens was doing, for pathological lesions often perform physiological experiments of a slowly progressive nature, which are difficult to reproduce in the laboratory.

- (4) With the diminution of the seborrhœa, the hair of the scalp becomes drier and "fluffy", as in the normal or pregnant female.
- (5) Dandruff ceases to form and may disappear without local treatment of the scalp.
- (6) The comedones shrivel, become desiccated, and may easily be picked out of the follicles with the finger-nail.
- (7) Pustules subside, and the indurated and cystic lesions gradually involute.
- (8) The growth of coarse hair on the face diminishes in vigour, so that daily shaving may be hardly necessary.

The patients, of course, develop a varying degree of gynæcomastia. The areolæ of the nipples become deeply pigmented, and on their surfaces may be seen droplets of sweat from the apocrine glands. All libido ceases, and disinclination for physical or mental activity may result. Return to normal, however, occurs rapidly after removal of the pellets. The acne may then relapse to some extent, but in my experience never seriously.

The possible effect of the treatment on spermatogenesis is a matter of obvious importance. Dr. Bishop has done sperm-counts in a few cases and they were normal, but we are both reluctant to advise this treatment except in cases in which severe disfigurement is likely to result from the acne, and in acne conglobata.

Dr. C. H. Whittle: Was there any evidence of tuberculosis in this case? I had a similar case in a thin, weedy man aged 40, whose buttocks were riddled with abscesses and sinuses for years. The infecting organism appeared to be a golden staphylococcus; but when portions of the lesions were removed at post-mortem, following his death from pneumonia, the sections showed a tuberculous structure with acid-alcohol-fast bacilli present.

Dr. Louis Forman: Before the implant the hair on the face was stiff and adult. It disappeared from the face while the implant was being absorbed, and has since grown again but is soft and fluffy.

The abscesses were examined bacteriologically. The acne bacillus and *Staphylococcus albus* were grown. No moulds were grown from the pus. Examination of the pus and of part of the wall of one of the abscesses revealed no evidence of tuberculosis.

Subcutaneous Nodules: For Diagnosis. ? Granuloma Annulare.—J. P. M. TIZARD, M.R.C.P. (for Professor A. A. MONCRIEFF).

W. H., female, aged 3 years 4 months. Perfectly well until April 1947, when lumps on the back of the head were noticed. Two weeks later two more lumps appeared in the palm of the right hand. The child did not complain of pain or discomfort. In June 1947, she appeared well, normal height but slightly underweight. Tonsils somewhat enlarged, but not infected. Small glands palpable in the neck and axillæ. Four nodules palpable in the left occipital region, one below the right axilla and two on the radial side of the right palm. A faint, circinate rash consisting of pale, pin-head papules was noticed on the abdominal wall (this has disappeared since). Thyroid slightly enlarged. No other abnormal clinical findings.

While in hospital for one week she was afebrile and there was no tachycardia. Red cell count 4,620,000. White cells 8,800 per c.mm. Eosinos. 5%. B.S.R. 7 mm. in one hour. X-rays: No evidence of calcification in the nodules; lung fields clear; heart—slight prominence in the region of the conus.

Biopsy report on one scalp nodule and the axillary nodule (Dr. M. Bodian).—The peripheral portion (fig. 1) of each nodule showed a large number of new capillaries and mainly perivascular collections of large rounded and elongated mononuclear cells as well as lymphocytes. Many of the mononuclear cells showed pyknotic nuclei with some mitotic figures, and there were a number of bi- and tri-nucleated cells present, but no large foreign-body giant-cell types. The central core of the nodule was much less vascular, and showed a definitely nodular arrangement of cells of similar types as above mentioned, as well as an increasing number of fibroblasts. Each nodule showed a degenerated central portion with few ghost-like cells and myxomatous and fibrinoid intercellular material (fig. 2). One of the degenerated areas contained a fair number of eosinophil leucocytes. The nearer the centre, the more collagen was laid down by the fibroblasts which in parts underwent myxomatous or fibrinoid degeneration (fig. 3). Nervous elements could not be found.

The general impression is of a very actively growing granulomatous lesion in the most peripheral or recently developed portions, and more fibrosis and degeneration in the more central or older parts of the nodule. These features indicate an allergic lesion, somewhat reminiscent of a rheumatic nodule.

Progress.—The nodules have increased slightly in size, and fresh nodules have appeared over the sixth and twelfth dorsal spines; at the junction of the sixth right costal cartilage and sternum and two additional nodules in the left occipital region. The nodules are about $\frac{1}{2}$ in. in diameter and are firm and painless. With the exception of those in the scalp and palm, the overlying skin is freely movable, but the nodules appear to be attached deeply. The child is still in good health; no evidence of carditis; eye examination, fundi and media normal; afebrile; hæmoglobin 96%; white cells 6,200, 1% eosinophils; B.S.R. 3 mm. in one hour; Blood Wassermann and Kahn reactions, negative; Mantoux 1/1,000, negative.

which I saw at St. John's Hospital. A section of one of the lesions in this case showed changes which were characteristic of granuloma annulare but Dr. Haber remarked in his report that they might equally be found in the nodules of rheumatoid arthritis. This patient had lesions on the forearms and fingers. Unfortunately, I saw her only once and omitted to ask her whether she suffered from rheumatism or not.

Both the case shown to-day and my case have lesions which are characteristic of rheumatic nodules, and each has one which is clinically suggestive of granuloma annulare.

These two facts, namely, histological and clinical similarity, do appear to point to the possibility of a common factor. There is, in addition, a characteristic third similar feature, that of distribution over bony prominences.

Dr. F. Parkes Weber: The similarity in the microscopic features of granuloma annulare and the necrobiotic nodules of rheumatoid arthritis, which was generally supposed to be unrelated by aetiology, is made more confusing still by a case like this important one of Dr. Dowling's.

Dr. A. C. Roxburgh: In 1936 I showed three cases of granuloma annulare at the meeting of the British Association of Dermatology (*Brit. J. Derm.*, 48, 633). One was typical, but one of the others had lesions on the elbows exactly the same as in Dr. Bowers' case and apparently also that of Dr. Dowling's, and they were diagnosed on the strength of the section as being granuloma annulare.

Acne Conglobata treated by Implantation of 300 mg. of Stilbæstrol.—**L. FORMAN, M.D.**

W. W., male, aged 21. (Previously shown at the meeting of the Section on March 20, 1947. *Proc. R. Soc. Med.*, 40, 699.)

At the age of 16 years he was six feet tall, plump, with well-developed genitalia and hair growth of the face and limbs. The skin of the face, chest and back was intensely seborrhœic with comedones, acne pustules and abscesses. In the armpits and perianal area, large deep abscesses communicated with each other, leaving epithelial bridges, and granulating, pus-covered ridges. The buttocks and perianal skin were grossly involved and indurated with subcutaneous abscesses and numerous sinuses.

Four years' continuous local treatment and general measures for his severe anæmia (Hb. 60%) led to some improvement.

In May 1947, Dr. Peter Bishop implanted 300 mg. of stilbæstrol, and to-day the effects of this treatment are to be seen. The skin of the face has become fine and delicate, and is no longer seborrhœic. The abscesses of the axillæ and perianal area are fewer, and the skin in these regions is less indurated. The breasts are enlarged, the external genitalia smaller, and he has lost his libido.

The pellet of œstrogen has probably been largely absorbed by this time, as is shown by the regrowth of fine, fluffy hair on the face. The areolæ of the breasts had become diffusely pigmented, but this pigment is now seen as patchy brown areas in the superficial layers of the epidermis, and is being desquamated.

Another interesting manifestation of the declining activity of the œstrogen is the flushing of his face, which was noticeable during the past month. He himself has been aware of this flushing particularly during the afternoon—a symptom comparable to menopausal flushing.

In this patient the effects of implanted œstrogens are observed—namely breast enlargement, shrinkage of the penis and probably the testicles, diminution in activity and size of sebaceous glands, and refinement and feminization of the skin. Œstrogen implant was suggested because of the severity of the disease although the reversal of the sexuality over a period of six to nine months is undesirable. Again it is known from experiments on rats that the germinal epithelium of the testes suffers severely. As far as I know sperm counts have not been carried out over the period of implant to determine if any permanent damage occurs in man treated with œstrogen implants.

However, this patient had been under constant treatment for four years, with periods up to a year in hospital. He was unable to work, and was showing the toxic effects of long-standing and extensive skin sepsis. At one time it was suggested that he might develop amyloidosis, for he lost a good deal of weight, developed an anæmia of 60% hæmoglobin and was going downhill.

Dr. H. W. Barber: I have had considerable experience of this method of treatment. In one case of acne conglobata, in whom the condition had been present many years and was associated with the so-called acne keloid on the neck and occipital region, the lesions in the groins and on the buttocks were very similar to those in Dr. Forman's case, and the constantly recurring deep abscesses made his life almost unbearable.

Subcutaneous implantation of stilbæstrol by Dr. Peter Bishop was followed by complete involution of the whole condition. Removal of the pellets was followed by some degree of relapse, but his condition was satisfactory when he was last seen.

Dr. Bishop has treated several cases of severe cystic acne for me by the same method. The effects on the skin may be summarized as follows:

- (1) The activity of the sebaceous glands is remarkably diminished.
- (2) The pilo-sebaceous orifices are reduced in size and are no longer easily visible to the naked eye.
- (3) The slight hypertrophy of the stratum corneum disappears, and the surface of the skin becomes smooth and delicate, like that of a child.

Dr. J. P. M. Tizard (in reply to a question): We have considered rheumatism very unlikely in view of the child's age, but we intend to keep her under observation.

POSTSCRIPT.—Dr. Dowling's remarks seem to provide the clue to the nature of these nodules, which are apparently the subcutaneous form of granuloma annulare.

A case, strikingly similar in its clinical and pathological aspects, was described by Grauer in 1934 (*Arch. Derm. Syph.*, 30, 785).

The following cases were also shown:

Acute Lichen Planus.—Dr. C. D. CALNAN (for Dr. I. MUENDE).

Necrobiosis Lipoidica (Sine Diabetes).—Dr. RONALD SCUTT (for Dr. J. L. FRANKLIN).

Erythrodermia Congenitale Ichthyosiforme.—Dr. G. B. MITCHELL-HEGGS and Dr. M. FEIWEL.

Mycosis Fungoides à Tumeurs d'Emblée.—Dr. C. H. WHITTLE.

? Pityriasis Rubra Pilaris. ? Darier's Disease.—Dr. R. M. B. MACKENNA and Dr. BERNARD GREEN.

Urticaria Pigmentosa.—Dr. F. R. BETTLEY.

(1) Epidermodysplasia Verruciformis (Lutz and Lewandowsky). ? Plane Warts resembling Lichen Planus Chronicus. (2) Acrodermatitis Chronica 'Atrophicans' (Herxheimer and Hartmann) (Presented as ? Berlock Dermatitis).—Dr. BRIAN RUSSELL.

(These cases may be published later in the *British Journal of Dermatology*.)

[January 15, 1948]

Histiocytoma.—ALICE CARLETON, M.D.

A healthy young woman has during the past six years, developed six small tumours on the thighs and upper arms. Each has followed an insect bite. The individual tumours are round, smooth and hard, brownish red in colour, and sharply defined on palpation. They grow slowly to a size of about 1.5 cm. and then remain stationary. No subjective sensation is felt. There is no family history of diabetes.

Senear, F. E., and Caro, M. R., 1936, *Arch. Derm. Syph.*, Chicago, 33, 209, reviewing 25 cases, found no significant connexion with sex or age. The usual site was the upper part of the limbs. Several followed minor injuries such as insect bites. They are usually single, only 4 out of 25 being multiple.

Arnold, L., and Tilden, I. L., 1943, *Arch. Derm. Syph. Chicago*, 47, 498, found a family history of diabetes in 50%.

The Chairman (Dr. A. C. Roxburgh): What is the best treatment?

Dr. Carleton: Excision.

Dr. F. F. Hillier : The histiocytoma was originally described by Pautrier and Woringer (1933, *Bull. Soc. franç. Derm. Syph.*, 40, 1659) who demonstrated the presence of fat and other bodies in the cells of many so-called fibromata; this phagocytic power showed that the essential cell was a histiocyte and not a fibroblast. I believe that one cannot differentiate absolutely between these two types of cell. The fibroblast, especially in the more primitive form found in tumours, given adequate stimuli may regain properties which it has lost in becoming specialized. Thus the primitive fibroblast may be capable of phagocytosis and be indistinguishable from the primitive histiocyte.

Four Cases by BRIAN RUSSELL, M.D.

Case I.—Dermatitis (Flavine) treated with Large Daily Doses of Crude Liver.

S. M., male, aged 41.

History.—1943: He received a severe wound, 8 in. by $\frac{1}{2}$ in., on the ulnar aspect of the left forearm. It was treated with sulphonamide powder. After four days he developed a rash which persisted for five months.

1947: He grazed his buttock and it was treated with flavine dressings. Cellulitis of the right thigh developed, and was treated with penicillin injections.

A symmetrical, follicular, crusted eruption appeared on his face, arms, legs and trunk.

Treatment.—Crude liver injections, 2 ml. daily for six days; and calamine lotion.

In less than a week the condition resolved leaving scaling erythematous remnants.

Then a slight follicular, papular recurrence was noted around the edge of the primary lesion and a few discrete papules on the forearms. A further injection of 4 ml. crude liver was given and the condition resolved.

Case II.—Seborrhæic Dermatitis with Exacerbation from Acriflavine.

M. B., female, aged 43.

History.—1938: She had "dermatitis" all over the body. She has had recurrences since at times of worry.

Dr. G. B. Dowling: An interesting feature of this case is the lesion of the palm and the question whether it is granuloma annulare. It has a whitish, papular, nodular appearance, whereas the other lesions are subcutaneous.

Dr. F. Parkes Weber: On the whole, the case seems to be one of "rheumatismus nodosus" of a chronic type, without as yet any articular rheumatism or cardiac involvement. The nodules in the occipital region are, clinically, especially characteristic. An interesting point is that microscopical

FIG. 1.— $\times 150$. Hæmatoxylin eosin.

FIG. 2.— $\times 63$. Hæmatoxylin eosin.

FIG. 3.— $\times 145$. Hæmatoxylin eosin.

FIG. 1.—Peripheral portion of a nodule showing a perivascular collection of large rounded and elongated mononuclear cells and lymphocytes.

FIG. 2.—A portion of a nodule showing the fibrinoid intercellular substance.

FIG. 3.—Higher power view showing radiation of fibroblasts round the central zone of degeneration.

examination of one of the lesions suggests at one part a necrobiotic nodule of rheumatoid arthritis. (The palmar nodules are an unusual, remarkable feature.)

Dr. R. E. Bowers: Coates and Coombs, in a paper on rheumatic nodules (*Arch. Dis. Childh.*, 1926, 1, 183), mention the occasional occurrence of multiple small subcutaneous "granules"; they conclude them to be of rheumatic origin, but say that they do not necessarily indicate a severe cardiac lesion.

Histologically, it may be difficult to differentiate an ageing nodule of acute rheumatism from that of chronic rheumatoid arthritis: both are sometimes indistinguishable from granuloma annulare.

Dr. F. Parkes Weber: It is imperative to keep this child for years under observation. The condition may be one in which the heart ultimately becomes involved.

Comment.—These cases are presented to show the value of daily high intramuscular dosage with crude liver extract in the treatment of sulphonamide and flavine dermatitis complicated by a generalized sensitization dermatitis. This condition tends to develop, as Gottschalk, H. R., and Weiss, R. S. (1947, *Arch. Derm. Syph., Chicago*, 56, 775), have observed with sulphonamides, when these substances, or flavine, are applied over relatively large areas of skin and particularly on damaged skin, and it seems to be necessary for a contact dermatitis from these agents to attain a certain critical size before generalized sensitization occurs.

The dermatoses produced by sulphonamides and flavine are very similar, if not identical, and other substances that can cause widespread sensitization with exudation include mercurials and paraphenylenediamine. With penicillin, a longer period of contact is usual before the development of sensitization, which also tends to be less severe and more localized.

Treatment by injection of liver, recommended as a routine procedure as a detoxifying measure in sulphonamide dermatitis by Abramowitz, E. W. (1944, *Arch. Derm. Syph., Chicago*, 50, 289), has been used in 33 consecutive cases of sensitization dermatitis from known causes, with the following results:

	Number of cases	Cleared 1-6 weeks (average 3 weeks)	Marked improvement 1-7 weeks (average 3½ weeks)	Slight improvement 2-3 weeks
Flavine	7	6	1	0
Sulphonamide .. .	7	6	1	0
Flavine and Sulphonamide .. .	3	3	0	0
Ammoniated mercury .. .	5	4	1	0
Paraphenylenediamine .. .	2	1	1	0
Penicillin	9	3	4	2

A control group has not been studied so that it is not possible to say how long these cases would have taken to resolve if treated in a different manner.

These figures refer to the secondary sensitization dermatitis. The primary lesions improve more slowly but also become dry, pale and scaly. Minor relapses after stopping treatment have also responded but results have been much less uniform with penicillin.

It is suggested that these conditions may represent states of disturbed metabolism from impairment of liver function arising from the absorption from extensive moist areas of substances known to be hepatotoxic. Breakdown products of cells and bacteria may also play a part ("autolytic eczema"), and Hartmann, F. W., and Romence, H. L. (1943, *Ann. Surg.*, 118, 402), noticed that in the treatment of burns in dogs, the use of wet dressings of tannic acid, silver nitrate, or ferric chloride, gave the highest incidence of liver degeneration or necrosis, and that degenerative changes even occurred after saline dressings. Dry applications of these agents were much less harmful.

The Chairman (Dr. A. C. Roxburgh): We know only too well the unfortunate results of the continued application of sulphonamides to the skin, but it is difficult to say anyone, other than a dermatologist, to realize the danger. Another point is that acriflavine aggravates sulphonamide dermatitis very severely. I am glad to learn that crude liver extract is so helpful because some of these cases are very resistant to treatment.

Dr. Louis Forman: Sensitization to antibiotics and antiseptics applied to the skin giving rise to a general eczematous dermatitis has been of frequent occurrence. The case of acriflavine dermatitis which responded so well to liver injections impressed me because in my experience a generalized dermatitis due to acriflavine runs a very prolonged course.

Dr. Russell believes that liver function may be disturbed in these cases of generalized dermatitis. However, it is possible that the epidermal cells when widely inflamed may not be able to absorb available vitamins in the amount normally present, or the demands may be greater. We know that extra vitamin C is required when there is widespread tissue inflammation.

The injections of liver may have supplied the skin with the increased amount of vitamin-B group which is needed by the epidermal cells.

I have had cases of exudative and lichenified dermatitis occurring on the scalp, face and elsewhere associated with evidence of gastro-intestinal disease, e.g. gastric or duodenal ulcer and Crohn's disease.

One old man with a fatty diarrhoea had extensive areas of lichenified dermatitis on the trunk and limbs. He had a severe high colour-index anaemia. There was no reticulocyte response to liver by injection so that it was not a true pernicious anaemia. However, plexan 2 ml. given daily produced a remarkable improvement in the skin condition. He remained well on monthly injections and then was put on to folic acid by mouth, the injections being stopped. It was hoped the folic acid by mouth would increase the absorption of vitamin-B group from the gut but he relapsed with papular lesions on the sites of the old areas of lichenification.

Dr. E. J. Moynahan: I wonder whether Dr. Brian Russell has any real evidence of interference with liver function. It is difficult to believe that substances as different as penicillin, acriflavine and

February 1947: Following a kick, she developed an ulcer on the ankle which has not healed since. The ulcer has been treated with penicillin ointment; adhesive bandages; cod-liver oil; and acriflavine, which helped at first but was then followed by profuse exudation.

On examination (17.12.47).—Marked pityriasis capitis. There was a seborrhœic type of eczema on the neck, upper lip, sternum, axillæ, antecubital areas, popliteal regions, and groins.

Treatment.—She was given injections of plexan 2 ml. twice weekly for one month; then once weekly for two weeks. Calamine liniment with ichthylol was also given.

She felt much better after the first injection and the bowels were more regular. The eruption became dry in one week. 31.12.47: There were faint, scaling remnants. She was to continue with vitamin B complex, or liver by mouth.

Case III.—Dermatitis (Sulphonamide) Treated with Large Daily Doses of Crude Liver.

R. K., male, aged 57.

History.—In 1947 he received a lacerated wound on the back of the left forearm just below the elbow. It was treated with penicillin powder (with sulphathiazole) and eusol.

An exuding rash developed around wound, spreading to the scrotum, calves, face, head and neck.

On examination.—There was a patchy, crusted erythema of the beard, in follicular pattern. A moist erythema for 2 in. around the wound, below the left elbow, with outlying follicular pustules. Peeling of the tongue, in geographical pattern. Scaling and œdema of the scrotum. Patchy, follicular, crusted erythema of the legs, and confluent behind the left knee.

Treatment.—Injections of plexan 2 ml. daily for six days, and calamine liniment.

In one week there was a striking improvement. All lesions were dry and subsiding. Face was almost clear; tongue clear. Two further injections of plexan 2 ml. were given in the next week.

Shortly afterwards he developed three furuncles on the knee. His doctor gave sulphonamide tablets, one twice a day. There was a severe recurrence. Face, head, forearms, and site of injury all exuded profusely again. The tongue became furred. He was given plexan injections 2 ml. daily for four days, after the second of which the skin was again dry. The tongue showed geographical areas of denudation: scaly remnants only in groin, and three resolving boils right inner knee. He was given calamine lotion.

After a week's improvement a slight tendency to relapse was noted on the forearms, with scaling patches. Plexan injections 2 ml. were given three times a week. These were continued for three weeks by which time the face was normal and the forearms and thighs were faintly scaling and pink.

Case IV.—Dermatitis (Flavine) Treated with Large Daily Doses of Crude Liver.

L. S., male, aged 33.

History.—In 1945 he received severe petrol burns on the face, arms, body and legs, when serving in the Middle East. He was treated with saline and acriflavine for ten days, without detriment, and the burns healed.

For eighteen months he has had a few spots and exudation behind the right knee, which he has treated with calamine lotion, but on one occasion he applied acriflavine. Shortly afterwards he developed a rash on the body, and has been attending hospital since, having various treatments; a patent ointment on one occasion aggravated the rash.

He then applied a dry yellow Army dressing to the back of the knee. The next day there was profuse exudation and, six days after the application, the rash spread to his face.

On examination.—Nervous and apprehensive. There was a golden-crusted, follicular erythema over the whole face and neck; a confluent, marginally follicular, crusted, exuding erythema of forearms; a confluent, exuding erythema in both popliteal spaces; a disseminated, discrete, follicular erythema on the trunk and the rest of the limbs; pompholyx of the hands. The tongue and mucosæ were normal.

Treatment.—4–5 ml. plexan daily for one week. Calamine liniment was applied to the lesions and light gauze dressings to the limbs.

After six days of treatment, the lesions on the face were all dry. The primary lesion behind the right knee was almost dry. The confluent, exuding erythema of the forearms had formed dry, golden crusts which were not disturbed but merely covered with a dry dressing which was removed a few days later, leaving a normal, dry, scaling surface beneath.

Progress.—When the face was quite clear and the forearms and legs much improved the dosage of plexan was reduced to 2 ml. daily.

When last seen the face was quite clear. There were dry, follicular papules, without erythema, on the forearms. The right popliteal space was dry and crusted in a small area.

treatment: ferrous sulphate gr. 3 b.d. and yeast extract gr. 5 with each dose of sulphetrone.

Progress.—Ulcer healing rapidly. Nasal swab: *My. lepræ* still present but in very small numbers.

FIG. 1.—Taken a few days after the commencement of treatment with sulphetrone.

FIG. 2.—Taken two months after the commencement of treatment with sulphetrone.

Blood-counts:—

	Before Treatment 2.1.48	During Treatment 15.1.48
Red blood cells ..	4,850,000	4,650,000
Hæmoglobin ..	97%	88%
Colour-index ..	1.0	0.94
White blood cells	14,000	14,800
Polymorphs ..	68%	59%
Eosinophils ..	—	2%
Basophils ..	—	2%
Lymphocytes ..	33%	33%
Monocytes ..	2%	4%

Biopsy (Dr. I. Muende).—There are numerous foci of dense collagen bundles among which there are many pale vacuolated fibroblasts. Between these foci there is a dense cellular infiltration composed of plasma cells, lymphoid cells and pale endothelial cells. In the superficial ulcerated area the vessels are dilated and engorged and surrounded by numerous polymorphs and lymphoid cells. Ziehl-Neelsen preparations show the presence of numerous acid-fast bacilli.

The following cases were also shown:

Multiple Idiopathic Hæmorrhagic Pigmented Sarcoma (Kaposi).—Dr. M. SKOBLO (for Dr. J. E. M. WIGLEY).

Two Cases of Necrobiosis Lipoidica Diabeticorum.—Dr. G. B. MITCHELL-HEGGS and Dr. M. FEIWEL.

(These cases may be published later in the *British Journal of Dermatology*.)

[February 19, 1948]

Pustular Eruption: for Diagnosis.—J. R. SIMPSON, M.B., M.R.C.P.

Mr. R. R., aged 59, a farmer.

History.—For the last four and a half years he has had an itching, pustular rash affecting the trunk, the lower part of the neck and the proximal parts of the limbs. The rash has not changed in its essential features, although it has waxed and waned, for no apparent reason, and he has had several almost complete remissions lasting for two or three weeks. He has

the sulphonamides can be responsible in the way he has suggested. It is also erroneous to draw conclusions from what happens to the liver in animals, because animals respond in a different way. Skin irritants have been shown to have an effect more on the stomach than on the liver. Finally, liver extract is not of much value in the treatment of hepatitis, except by way of vitamin supplement.

Dr. Brian Russell: In reply to Dr. Moynahan, in my opinion tests of liver function are so insensitive as to be of little value. A liver puncture would give the information required but I do not consider the risk is justified, particularly as flavine and sulphonamides are known to be absorbed, for example, from burns, and have been reported to cause liver damage and even necrosis. Regarding penicillin sensitivity, I would suggest that there is an increasing number of individuals who have been sensitized by the use of sulphonamides and flavine, so that they suffer from a subclinical hepatic insufficiency and react unfavourably to relatively milder agents.

Dr. R. M. B. MacKenna: Acriflavine before the war was usually considered a safe application, and now we regard it as a fairly dangerous one. The incidence of dermatitis caused by weak alkalis, particularly on the hands of middle-class women, seems to be rising, and our skin resistance to these relatively innocuous chemicals seems to be dropping. If this is so it is a serious matter for the community as a whole. In one of the cases exhibited to-day the patient told me that when there was a flare-up he applied a dry military dressing which he said contained acriflavine. I asked him why he thought it contained acriflavine, and he replied that it was because it was yellow; but it might equally have contained picric acid, which will provoke a similar eruption and a rather more severe one.

Dr. G. B. Mitchell-Heggs: Before we accept this thesis *in toto*, we should bear in mind similar cases which have benefited in a dramatic fashion by injections of other foreign proteins.

I gather that the liver has to be severely damaged before this can be detected by liver tolerance tests or be improved by parenteral liver extract therapy.

Cirrhosis of the liver is now rather uncommon. When I was a student it was more common, but I only recall a few who were having treatment for a skin condition. In addition I have seen similar cases of seborrhœic dermatitis respond to vaccine therapy and the elimination of septic foci and chronic anxiety.

We are seeing more patients to-day suffering from conditions of the skin, which are in some way associated with deficiencies in diet. One finds that many improve on an increase of vitamins A, B-complex and D.

Dr. F. F. Hellier: Before we accept these results we must be careful that there are not other factors playing a part, such as the effect of admission to hospital which, at least in one case, occurred synchronously with the commencement of the injections; one must also allow for the enthusiasm of the dermatologist, which has a good effect on the patient whatever he does for him. I saw, as many of us did during the war, an enormous amount of resistant sulphonamide dermatitis, and yet it could not be said that our soldiers were ever short of food or vitamins. Indeed, they had never been better fed in their lives. Therefore I do not think that shortage of food can be the cause of either the supposed increased incidence or resistance of cases of dermatitis. Nowadays more people are exposed to chemotherapeutic substances than before the war, when not many of these synthetic preparations were available. We see more housewives now suffering from dermatitis for the simple reason that the modern housewife, if she gets a dermatitis, can no longer find a neighbour to do her washing. Before the war there were various ways by which she could avoid any work which irritated her condition but now she has to carry on as best she can; in addition she is exposed to many new chemicals capable of producing dermatitis.

One sees a lot of penicillin dermatitis nowadays, and yet in the first two years during which penicillin was used in the country we hardly saw any at all. I do not know what the explanation is, whether it is some alteration in the penicillin or in the base, but I do not think it can be attributed to deficiency of diet as the same thing is happening in America.

Dr. Brian Russell: I may be too hopeful about these cases, but some of the patients describe relief from depression, anorexia, and constipation, in addition to the improvement in the skin condition. The continued improvement is far in excess of that noted after the use of T.A.B.

In reply to Dr. Hellier, I confess the treatment has been given with enthusiasm, but the treatment of the first case was carried out by Dr. A. J. Nicholas, who, following his experience of conditions of malnutrition in Burma, employed a much higher dose than we were giving at that time. Only 8 of the 33 cases were treated as in-patients.

Leprosy.—A. I. SUCHETT-KAYE, M.D. (for A. H. HARKNESS, M.R.C.S.).

A Chinese seaman, aged 41, with a history of syphilis two years previously, was sent to the V.D. Dept. of St. Peter's Hospital (9.12.47) with a diagnosis of gumma. The previous history showed that two weeks before admission a gangrenous-looking vesicle appeared just below and on the anterior aspect of the left knee and when first seen it had developed into a deep punched-out ulcer, 2 in. by 2½ in. Scrapings from both the ulcer and nasopharynx were positive for *My. lepre* and negative for *S. pallida*, Vincent's organisms, Ducrey's bacilli, Leishman-Donovan bodies and *C. diphtheriæ*.

Central nervous system.—Paræsthesia involving the facial nerves. Sensory loss to pin-prick corresponding to C6, C7, C8, L4 and L5. C.S.F. normal.

Treatment.—Sulphetrone (B.W. & Co.) 1 gramme six-hourly by mouth. Blood levels, carried out by Dr. G. Brownlee on two occasions, were 3.0 mg. per 100 ml. Adjuvant

treatment: ferrous sulphate gr. 3 b.d. and yeast extract gr. 5 with each dose of sulphetrone.

Progress.—Ulcer healing rapidly. Nasal swab: *My. lepræ* still present but in very small numbers.

FIG. 1.—Taken a few days after the commencement of treatment with sulphetrone.

FIG. 2.—Taken two months after the commencement of treatment with sulphetrone.

Blood-counts:—

	Before Treatment 2.1.48	During Treatment 15.1.48
Red blood cells ..	4,850,000	4,650,000
Hæmoglobin ..	97%	88%
Colour-index ..	1.0	0.94
White blood cells	14,000	14,800
Polymorphs ..	68%	59%
Eosinophils ..	—	2%
Basophils ..	—	2%
Lymphocytes ..	33%	33%
Monocytes ..	2%	4%

Biopsy (Dr. I. Muende).—There are numerous foci of dense collagen bundles among which there are many pale vacuolated fibroblasts. Between these foci there is a dense cellular infiltration composed of plasma cells, lymphoid cells and pale endothelial cells. In the superficial ulcerated area the vessels are dilated and engorged and surrounded by numerous polymorphs and lymphoid cells. Ziehl-Neelsen preparations show the presence of numerous acid-fast bacilli.

The following cases were also shown:

Multiple Idiopathic Hæmorrhagic Pigmented Sarcoma (Kaposi).—Dr. M. SKOBLO (for Dr. J. E. M. WIGLEY).

Two Cases of Necrobiosis Lipoidica Diabeticorum.—Dr. G. B. MITCHELL-HEGGS and Dr. M. FEIWEL.

(These cases may be published later in the *British Journal of Dermatology*.)

[February 19, 1948]

Pustular Eruption: for Diagnosis.—J. R. SIMPSON, M.B., M.R.C.P.

Mr. R. R., aged 59, a farmer.

History.—For the last four and a half years he has had an itching, pustular rash affecting the trunk, the lower part of the neck and the proximal parts of the limbs. The rash has not changed in its essential features, although it has waxed and waned, for no apparent reason, and he has had several almost complete remissions lasting for two or three weeks. He has

not been taking patent medicines. Erysipelas of the face twenty years ago. Right inguinal hernia and varicocele treated surgically in 1945.

On examination.—The eruption is symmetrical. It is most profuse on the whole of the trunk, but is also present on the lower part of the neck, the shoulders, the upper half of the arms and on the thighs; the buttocks and the sacral and olecranon areas being spared. It is composed chiefly of pustules, 2 to 4 mm. in diameter, each with an erythematous halo, and red macules covered with yellow scales and crusts. A few clear vesicles surrounded by normal skin can also be seen. The lesions are grouped in some places, but do not all show the same stage of development in any one area.

He is edentulous and no abnormality was found in the heart, lungs, abdomen, or central nervous system.

Investigations.

Blood-count normal.

Contents of pustule.—Gram film: No organisms seen. Leishman film: Neutros. 98.5%; lymphos. 1.0%; eosinos. 0.5%.

Cultures (blood-trypsin-agar) sterile after forty-eight hours.

Mantoux reaction negative—1:1000. Wassermann and Kahn reactions negative.

Biopsy.—Section shows oedema of the epidermis and a vesicle containing polymorphs beneath the stratum corneum. There is a scanty leucocytic infiltration of the epidermis and corium. There is no preponderance of eosinophils.

X-rays: Chest—nothing abnormal. Nasal sinuses: mucosal thickening of both antra and a polypus in the left antrum.

Tonsillar swab.—Streptococci, viridans type: light growth. *M. catarrhalis*: moderate growth. No hæmolytic streptococci or diphtheria bacilli grown.

30.12.47: Bilateral antral puncture and wash-out with evacuation of mucopus (Mr. Phillip Scott). This was repeated twice without finding pus and no further treatment advised for the nose.

Treatment has also included sulphapyridine 0.5 gramme t.i.d. for seven weeks and liq. arsenicalis minims 5 t.i.d. for two weeks; these had no effect on the rash.

Dr. P. J. Feeny: Now that more success is being obtained in culturing viruses, I wonder if one should seriously consider culturing cerebrospinal fluid from this type of case and from cases of pemphigus and dermatitis herpetiformis with a view to locating a possible virus.

Dr. W. Lemberger: Since 1872 when impetigo herpetiformis was first described many atypical cases taking a less malignant course have been reported. If one is prepared to regard this case as belonging to this group of pustular eruptions one would have to remember from the therapeutic point of view that in some cases a definite endocrine relationship appears to exist. I am referring to cases with signs of hypoparathyroidism in which dihydrotachysterol, A.T.10, proved helpful.

Dr. Ivan H. McCaw: I have been looking after a boy of 10 who has a condition very similar to this. He has recurrent vesicles which become turbid; they do not extend, but they dry up and in a week or two the scabs fall off. The findings have been exactly similar to those described by Dr. Simpson. I have had impetigo herpetiformis in mind, and dermatitis herpetiformis. The boy has tinea amiantacea on the scalp, which quickly clears up with treatment but recurs, and whether this has anything to do with his body condition I do not know.

The President: I would suggest that heavier doses of arsenic should be tried before concluding that he does not respond to it.

Tropical Lichenoid Dermatitis.—P. D. SAMMAN, M.R.C.P. (for S. HARDY KINGSTON, M.B.).

T. G., aged 47, seaman.

History.—According to the patient quite fit until October 11, 1947, when his feet suddenly became swollen and at the same time he developed a rash on his face and limbs which consisted of spots like those now present on his arms, but larger. At about the same time patchy pigmentation appeared and the skin of his back and buttocks became roughened.

He was taken ashore and admitted to a hospital in Santa Domingo, the condition being diagnosed as fish poisoning. In hospital the rash cleared and he was returned to his ship after one month, when the rash recurred almost immediately. He returned to this country in December and reported to the out-patient department at the end of January, complaining of disfigurement.

Mepacrine history.—The patient had never taken mepacrine until July 1947 but from then he took it continually until he was admitted to hospital; at times he was upset by it. On return to his ship he had to take a double dose to make up for the days lost in hospital. He continued to take it until he returned to this country.

Examination shows the yellow staining of mepacrine, especially on the abdomen; there is also a patchy macular pigmentation of the whole body and some areas of depigmentation.

There are a few lichenoid papules on the arms and some papules below the eyes due to follicular plugging. Over the greater part of the back and buttocks there is a severe degree of follicular hyperkeratosis, resembling lichen spinulosus.

The pigmentation and follicular hyperkeratosis are less now than they were a month ago.

Investigation (23.1.48).—W.R. and Kahn negative.

Blood-count: R.B.C. 5.51 million; Hb. 110% (Haldane); C.I. 1.0; W.B.C. 12,400, neutros. 80%, eosinos. 4%, lymphos. 9%, large monos. 7%.

Urine normal.

Dr. W. G. Tillman: Those in the Services saw a number of lichenoid eruptions due to mepacrine. I can remember one with the same form of spiny eruption. I should have thought the papules on the forearms, neck and face and legs were compatible with the diagnosis, though it did occur to me that the pigmentation on the chest and the patches on the upper arm might be tinea versicolor and I would suggest a scraping being examined.

Dr. R. M. B. MacKenna: I thought of pityriasis versicolor when I saw the colour of the skin. I have not seen lesions resembling lichen spinulosus in so-called tropical lichenoid dermatitis but I know they have been described. In this case there are two forms of follicular lesions, viz. spiny and rounded. Possibly the latter are a sign of avitaminosis. It has been suggested in the American literature that in tropical lichenoid dermatitis there may be some fault of the gastric or intestinal mucosæ whereby there is faulty absorption of vitamin A. I would like to ask whether anyone examined the patient's finger nails under a Wood's ray? I have not had the opportunity of making this examination but I believe that in patients who have been taking mepacrine the nails show an unusual type of fluorescence.

Dr. Samman: Scrapings for fungus have not been made. I did, however, examine him under the Wood's light and except for the extraordinarily beautiful colour of his hair from some oil he was using, he showed nothing at all. He has improved during the month we have had him under observation. He has had large doses of vitamin A and a good diet.

POSTSCRIPT.—Scrapings from the pigmented areas have subsequently been examined but no evidence of tinea versicolor or other fungus has been found.

Leprosy Treated with Sulphetrone in 1943.—A. H. HARKNESS, M.R.C.S., L.R.C.P., and G. BROWNLEE, Ph.D.

Man, now aged 53.

Lived for seven years in British Guiana and during 1927 was employed for some months in the erection of an electric light plant and a cinema in a leper colony. The patient, whilst travelling by air in 1934, became aware of areas of anæsthesia on the extensor aspect of the left thumb and forearm but a diagnosis of leprosy was not made until a year later in Jerusalem. Previous treatment consisted of weekly injections of iodized moogrol.

When first seen by us there were multiple nodules, a trophic ulcer on the right foot and nervous involvement of the chest and upper and lower limbs. An excised papule showed a typical histological picture with large numbers of *My. lepræ*, and nasal swabs were also positive. Treatment with sulphetrone by the mouth commenced in October 1942. A dosage of 1.5 grammes for five days was gradually increased to 6.0 grammes daily, and for a short period 7.0 grammes daily were taken; fluids were restricted to 3 pints (1.7 litres) daily. The drug was administered continuously over a period of fifteen months. Adjuvant treatment consisted of ferrous sulphate 3 grains twice daily. There were no toxic manifestations. Hæmoglobin, averaging 70%, fell on one occasion to 60% and blood levels of sulphetrone varied between 2 and 3 mg. per 100 ml.

All nodules were absorbed during treatment and no fresh ones have appeared. Nasal swabs became negative after twelve months' treatment and have remained so.

There has been no extension of nervous involvement and the same areas show anæsthesia but tactile sensation in the fingers has improved as shown by the fact that the patient is now able to count and distinguish coins in his pocket. The general health of the patient has improved considerably and he has put on weight.

Several reports from Nigeria and India have recently appeared concerning the good results obtained with sulphetrone in the treatment of leprosy and we thought it would be interesting to show the first case treated with this preparation.

Dr. G. Brownlee: The interest in drugs of the "sulphetrone" type arose from the demonstration of the potent antibacterial activity of diaminodiphenylsulphone described by Buttler and others in 1937. It was the chemotherapeutic efficiency of the drug which stimulated our chemical colleagues to prepare a series of derivatives which would retain the activity but without the toxicity of the parent compound. Between 1936 and 1940, a series of Schiff's bases had been studied and appeared to give a favourable lead. Two derivatives, piperonylidene- and cinnamylidene- diaminodiphenylsulphone, justified a complete pharmacological study. They proved satisfactory from the antibacterial aspect, particularly against acid-fast organisms, but had to be rejected because of their tendency to produce peripheral neuritis. However, the progress made justified the testing of soluble derivatives which might prove to be free from these defects, and my attention was directed to a soluble derivative first prepared in 1936. This was sulphetrone. Its chemical name is tetrasodium

4: 4'-bis (γ -phenylpropylamino)-diphenylsulphone- α : γ : α' : γ' -tetrasulphonate. It is insoluble in alcohol and other organic solvents but is exceedingly soluble in cold water. Brownlee, Green and Woodbine (1948) described its structure, chemical and physical properties, its pharmacology, experimental therapy and possible clinical uses. This was followed by a description (Brownlee and Kennedy, 1948a) of the suppressive effect of sulphetrone on progressive experimental tuberculosis in groups of guinea-pigs. The drug was found to be bacteriostatic in action. In a second study (Brownlee and Kennedy, 1948b) showed sulphetrone to be more efficient than promin in protecting the laboratory animal against experimental tuberculosis and to be synergic with streptomycin. The combined effects were impressive enough to justify a clinical trial, unfortunately restricted to a limited series (Madigan, Swift, Brownlee and Payling-Wright, 1947). Simultaneously the drug was under test against leprosy, the case shown to-day being one of the first. Others have been described by Muir (1948) and by Wharton (1947).

The drug has four sulphonated side chains and is a large molecule. Unlike other diaminodiphenylsulphone derivatives, sulphetrone is not hydrolysed in the body; it is therefore well tolerated and may be exhibited continuously for long periods. This patient has had continuous drug therapy for fifteen months. However, sulphetrone has well-defined hematotoxic actions of an interesting kind. It is capable of reacting with alimentary iron to give a non-absorbable complex and thus inducing a hypochromic anemia. This may be prevented by the administration of adequate amounts of oral iron. Sulphetrone is incompletely absorbed and thus is capable of modifying the micro-flora of the gut. Since biosynthesis is frequently a limiting factor in the supply of essential components of the B vitamin complex, alteration of the flora may cause deficiency states. One is an anemia of nutritional origin. It was discovered that simultaneous administration of fresh yeast prevented its development. A third anemia, a hemolytic anemia associated with crenation of red cells and increased fragility, is caused by drugs of this kind. It is continuous during the period of exhibition and may result in a fall of circulating haemoglobin corresponding to 60% Haldane in extreme cases.

The chemotherapy of acid-fast organisms should logically employ the highest blood concentrations that are tolerated by the patient, with the possible advantage of shortening the time of recovery and avoiding the development of resistant strains. Both Muir (1948) and Wharton (1947) gave smaller doses than those employed by Harkness. However, at the blood concentrations employed by all three workers, the problems of toxicity I have mentioned become minute.

An interesting clinical point is that Harkness, treating an intelligent patient, was able to leave the details of drug dosage to his patient.

Dr. J. A. O'Connor: Some speakers mentioned the activity of sulphetrone against the tubercle bacillus. Is it not possible that a simpler compound such as para-amino-salicylic acid, which is now being tested in tuberculosis, would be equally efficacious in cases of leprosy? The molecule is much simpler, and the drug appears to be tolerated in very considerable doses, even as high as 10 to 15 grammes a day by mouth. Blood concentrations can be got up to 10 or 15 mg. per 100 ml. of blood. Para-amino-salicylic acid is excreted very rapidly without producing toxic side-effects and I wonder whether Dr. Harkness or Dr. Brownlee has considered the possibility of using some substance such as this in the treatment of leprosy.

Dr. Brownlee: We are only at the beginning of the chemotherapy of this difficult group of organisms and we have all been interested in the report on the chemotherapeutic action of para-amino-salicylic acid. Of course, its application should be encouraged. It should prove a cheaper drug than sulphetrone to make and, should clinical trial prove it to be effective against *Mycobacterium tuberculosis*, it is likely to prove more effective against *My. leprae*.

Dr. O'Connor: This particular drug appears to be unusually potent. I saw some microscopic slides recently from a case of tuberculous empyema. The preliminary slide showed the pleural fluid to contain many polymorph-leucocytes, and thousands of tubercle bacilli were floating free in the liquid. The patient suffered from a bronchopleural fistula for which she was receiving penicillin; 2 grammes of para-amino-salicylic acid had been injected into the empyema. Examination of the empyema fluid a week later showed that 82% of the tubercle bacilli had been phagocytosed. Whether this was due to the combination of the drug with penicillin I do not know, but the fact remains that there was this marked degree of phagocytosis and perhaps the same thing could occur in other diseases due to acid-fast bacilli.

The following case was also shown :

Erythema Elevatum Diutinum.—Dr. E. LIPMAN COHEN.

(This case may be published later in the *British Journal of Dermatology*.)

[January 16, 1948]

DISCUSSION ON THE MANAGEMENT OF UTERINE INERTIA IN THE FIRST STAGE OF LABOUR

Mr. D. M. Stern: Uterine inertia is a condition occurring in the course of labour when the contractions are demonstrably weaker, less frequent or shorter than normal. During the first stage of labour the effect of the contractions is to dilate the cervix; therefore when inertia is present this dilatation proceeds more slowly, leading to prolongation of labour. Arbitrarily, it may be assumed that when labour lasts more than twenty-four hours some degree of inertia is present. There is some difficulty in assessing the length of labour. Generally it is measured from the onset of painful uterine contractions, a subjective symptom not always coincident with the beginning of labour which, theoretically, should be measured from the start of the dilatation of the cervix.

Divergent opinions are found in the textbooks as to the cause of inertia, its treatment and results. Therefore, these remarks are based on the experience of a series of some 5,000 cases.

The causes may be summarized: (a) Badly fitting presenting part; malpresentation and deformity of the foetus; abnormalities of the birth canal, including placenta prævia; prematurity, hydramnios and twins; small head in a large lower segment. Over-distension of the uterus is not a factor here. (b) Psychological causes—fear and ignorance. (c) Congenital causes—hypoplasia of the genital organs. (d) Hormonal. (e) Age, especially in primiparæ. (f) Multiparity—not seen much to-day in this country. (g) Drugs and poisons, especially early in labour. (h) Accidental antepartum hæmorrhage. (i) Full bladder and bowel. *Alleged causes:* (a) General debility and disease—no evidence of this in the present series. (b) Early rupture of the membranes tends to increase rather than reduce uterine contractions. When associated with inertia the latter is due to a badly fitting presenting part. (c) Fibroids—only when associated with age, hormonal or congenital causes. (d) So-called rigid cervix—probably the result of hypertonic type of inertia.

Treatment.—(a) Prophylactic; correction of abnormal presentation. Removal of fear and ignorance. Attention to bladder and bowels. (b) Active treatment—not practised in the present series. (c) Passive treatment—rest, food, drink, sedatives (chloral, pethidine, morphia, pentothal); attention to bladder. Present condition of the patient should be treated and the length of labour ignored.

	Primiparæ			Forceps		Total foetal mortality		Maternal mortality
Total deliveries	23,051	13,528	58.7%	1,552	6.7%	1,498	6.5%	61
No. of labours								
over 24 hours	4,854	3,692	76.1%	785	16.2%	312	6.4%	11
24-48.. ..	3,625	2,623	72.4%	498	13.7%	204	5.6%	6
48-72.. ..	851	725	85.2%	171	20.1%	50	5.9%	2
72-96.. ..	252	230	91.3%	74	29.4%	32	12.7%	3
96-120.. ..	79	73	92.4%	26	32.9%	21	26.6%	0
120 and over..	47	41	87.2%	16	34.0%	5	10.6%	0

Professor H. J. Drew Smythe: For the management of inertia in the first stage of labour, it is necessary first to determine the type of inertia present.

There are three main types of primary inertia. The first is characterized by ineffectual contractions from the commencement of labour. Pains are poor, and may continue so for several days. The presenting part is well adjusted to the lower segment, and the membranes do not rupture early. Contraction and retraction are feeble. This is true primary inertia.

The second is the "colicky" uterus described by Miles Phillips. The patient has strong painful contractions from the commencement of labour. Nevertheless the cervix is slow to dilate, the membranes rupture early and the onset of foetal and maternal distress is common. This type of inertia is often associated with posterior positions of the vertex, and with the android pelvis. It is due to loss of polarity of the uterus.

The third type is that which is associated with fear. From an early stage of labour, the patient becomes hysterical, and calls out for immediate delivery. There is no relaxation by the patient between pains, and during them she uses every voluntary muscle against the uterine forces. There is inhibition of cervical dilatation by the higher centres.

In treatment of the first type, the prolonged use of sedatives only worsens the condition. It is essential that these patients should remain active during the day, and a sedative be given

only at night, to ensure sleep. Usually the cervix will dilate gradually, but it may take several days; there is no danger as long as the membranes remain intact. If the membranes do rupture, then our anxiety is increased, and intervention may be necessary. Once the cervix is fully dilated, forceps delivery is indicated. Special care must be taken during the third stage, as again inertia may be experienced. The placenta should not be allowed to remain *in utero* for more than two hours, as definite shock is associated with its retention beyond this limit.

In the second type, sedatives are definitely indicated throughout the first stage. The usual mixture of pot. brom., chloral and tr. opii at three-hourly intervals is helpful in the early stages. Nembutal and other barbiturates can be used instead at this stage. When the cervix has reached quarter dilatation, pethidine in combination with chloral gives good results. With the onset of foetal or maternal distress, further management depends on the cervical dilatation. If the cervix is half-dilated, then manual dilatation is usually successful. If dilatation is not up to half, then incision of the cervix or cesarean section is indicated.

In the third type, if one could detect this from early pregnancy, treatment should commence at once by lessons in relaxation, and by gaining the patient's confidence. It is most important in all cases, and especially so in this third type, that the patient should be, during the antenatal period, in the care of the obstetrician who is to attend her at the confinement. This type may, sometimes, be foreseen, or may come as a complete surprise when labour commences.

Treatment of these cases is by explanation of what is occurring, and the necessity of the process, and by the giving of sedatives. Morphia is indicated at night, twilight sleep is an alternative. On full dilatation, early application of forceps is often indicated owing to the importunity of patient or relatives.

Secondary uterine inertia may occur during the first stage, but is almost certain to be due to disproportion, and operative interference is necessary.

Mr. J. V. O'Sullivan: Inertia means the prolongation of labour over thirty hours. A cardinal sign of inertia is slow dilatation of the cervix which in bad cases remains at 2-3 fingers for three or more days. Dilatation of the colon is also well marked in severe cases.

Treatment.—In all cases of inertia a cause should be sought and disproportion excluded. If disproportion is present the treatment is often surgical, but apart from these cases medical treatment will succeed in the great majority of patients. All cases of inertia should be treated as test labours, and given plenty of glucose and carbohydrates to prevent acidosis, and tests should be made regularly for acetone in the urine.

Only mild sedatives such as pot. brom. 20 grains, and chloral hydrate 30 grains, should be given during the first stages, but later pethidine 100 mg. should be added. The administration of sedatives should be avoided for as long as possible. Morphia should never be given as a routine. It is essential, however, in cases due to fear, tonic uterine contraction, or for cases with ruptured membranes and severe constant backache.

Patients suffering from inertia should be given all possible encouragement and attention, a treatment described by Smellie as "beguiling the patient".

Uterine stimulants.—An ordinary oil bath and enema are useful in many cases, but should not be repeated. Oestroform, up to 100,000 units, is an aid in some cases associated with prematurity or postmaturity. Pitocin, 1 to 2 units half-hourly, may be given when the membranes are intact and there is no foetal distress or disproportion.

Sepsis.—Sepsis should be prevented or controlled by giving sulphonamides and penicillin as a routine to all cases of inertia.

After seventy-two hours the danger of foetal and maternal distress, if not already present, is imminent and the risk of cesarean section increases. Hence on the third day a complete obstetric examination should be carried out including an antero-posterior and lateral X-ray examination. A catheter specimen and vaginal swabs should be sent for examination.

Surgical treatment.—(1) Continuous traction is useful occasionally but more especially is it used when the child is dead.

(2) In cases where the cervix is thin, stretched and 2 to 3 fingers dilated, the pains weak and regular, no disproportion expected at the outlet, the head deeply engaged (almost on the perineum), and the mother or baby showing signs of distress, I recommend *cutting the cervix* at 9 and 3 o'clock for half an inch each side and then gently pushing the cervix up, especially in front. No anæsthetic is necessary, or at most only gas and air. Some of these patients deliver themselves spontaneously in six to eight hours, others require a low forceps.

(3) Where there is foetal or maternal distress which necessitates immediate delivery, I recommend a large medio-lateral *perineotomy* then, under direct vision or under touch, I again cut the cervix, if 3 fingers dilated, at 3 and 9 o'clock, but if only 2 fingers at 12, 8 and

4 o'clock. In each case the incision should be taken to the lateral fornix taking special care not to cut the vaginal wall as the fornix is approached. This part of the operation is sometimes difficult. I then apply forceps and deliver, first doing manual rotation where necessary.

(4) Cæsarean section has only very limited use in the treatment of inertia. It is obviously necessary for all cases of disproportion with early maternal or foetal distress.

I usually perform a lower segment transverse incision in the uterus except in cases of contraction ring, general tonic contraction and certain cases where the foetus is very large and the head fixed firmly in the brim with little liquor in the uterus, when I do a so-called lower segment vertical incision. There is no doubt in my mind that cutting of the cervix in suitable cases in young women is better than cæsarean section.

In some cases where the child is large and post-mature and the widest diameter not through the brim, the cervix thick and not more than 2 to 3 fingers dilated, I recommend lower segment cæsarean section even where the child is dead, because I believe it is safer and better for the mother. I believe G. F. Gibberd agrees with this method of treatment in suitable cases.

Professor W. C. W. Nixon: Until recently it was difficult, if not impossible, to assess the activity of the uterine muscle at a three dimensional level—centimetres, grammes, seconds. This is now possible with Lorand's tocograph (1947). It is now possible even for the un-initiated to measure uterine action with accuracy especially when Lorand's more recent instrument, the tocometer, is used. Professor Douglas Murphy (1947) obtained his results with Lorand's earlier model and not with the improved tocograph.

Tables I, II, III, have been prepared by Mr. Ian Fraser, Obstetric Registrar at University College Hospital. The figures represent the years 1946 and 1947 together.

TABLE I.—PROLONGED FIRST STAGE OF LABOUR
Incidence at University College Hospital in the Years 1946-1947

Total number of deliveries	2,385
Cases with prolonged first stage of labour (more than 48 hours)	182 (7·6%)
Average length of first stage in these cases (longest first stage 171 hours)	69·4 hours

TABLE II.—PROLONGED FIRST STAGE OF LABOUR
Course of Labour in 182 Cases. Compared with all Deliveries over Years 1938-1947

	Prolonged first stage of labour 1946-1947		All deliveries 1938-1947
Number of infants delivered	186	9,770
Spontaneous delivery	135	89·8%
Forceps	33	6·5%
Cæsarean section	18	3·8%
Incidence of cæsarean section for uterine inertia	{ 1946 5% 1947 13%		

TABLE III.—FOETAL MORTALITY IN PROLONGED FIRST STAGE OF LABOUR
Comparison of Mortality in 182 Cases of Prolonged First Stage in 1946-1947, with Mortality of all Infants Delivered 1938-1947

	Prolonged first stage of labour 1946-1947		All deliveries 1938-1947
Infants delivered	186	9,770
Total infant mortality	8*	5·9%
Stillbirths	7*	3·8%
Neonatal deaths	1	2·1%
(3 of above infants died late in first stage)			
Where membranes ruptured over 24 hours prior to delivery—			
Cases	45	
Infant mortality	3*	6·7%

*Includes one infant with gross congenital abnormality.

Prophylactic treatment.—Uterine inertia has its highest incidence among primipara. Encouragement, sympathy, explanation and the administration of the proper sedative at MAY—OBSTET. 2

the right time can do much to allay fear and remove the inhibiting effect this has upon the dilatation of the cervix. Active movements in the early part of the first stage should be encouraged. Fluid balance and the nutrition of the parturient woman need to be carefully controlled.

Treatment of established uterine inertia.—For long it has been the practice to administer sedatives. In many instances after a period of mental rest the woman has proceeded to deliver herself normally.

Pituitary extract.—The haphazard use of this powerful drug is rightly condemned, but there does seem to be a place for it in selected cases of uterine inertia. By the use of Lorand's tocograph it is possible to determine which case would benefit from such treatment. In the presence of disproportion, malpresentation, excessive parity, the drug is dangerous. Again if the tracing shows the uterus to be in a state of hypertonic inertia an oxytocic drug should never be given. It is when the tracing shows hypotonic inertia (low resting tone, infrequent contractions with a low amplitude) that the case is an ideal one for this therapy. The effect of the first injection (pitocin 1 unit) is seen within a few minutes and the time when the next injection should be given will be clearly indicated. Lorand's classification of inertia into hypotonic, normotonic, hypertonic is of practical value. The tocograph has revealed that there is a type of inertia associated with hypertonus of the uterus that usually has to be terminated by operative delivery.

The effect of pitocin (2 units) when given in the first stage of labour will be seen from the following tracings:

FIG. 1A.—39 years, para-0, normotonic inertia. Pitocin (2 units). Spasm followed by normal rhythm, seventeen hours after labour onset and sixteen hours before delivery.

FIG. 1B (Same patient).—Normotonic inertia. Pitocin (1 unit in 1 c.c. sterile water). No effect.

FIG. 2.—30 years, para-0. Pitocin (2 units) eighteen hours after labour onset, twenty hours before delivery. Resting tone and contraction frequency increased.

FIG. 3.—30 years, para-0. Hypotonic uterus. Pitocin (2 units) injected twice, twenty-one hours after labour onset, delivery three hours after last injection.

Eastman (1947) gives pituitary extract (initial dose $\frac{1}{2}$ minim and repeated at half-hourly intervals) only after labour has been stationary for eighteen to twenty-four hours with the os dilated 3 to 4 cm. Disproportion and multiparity are contra-indications.

Operative interference.—This can be considered under three headings: (1) Rupture of the membranes; (2) Dührssen's incisions and instrumental delivery; (3) Cæsarean section.

Every case in which there has been active labour for twenty-four hours should be carefully reviewed with regard to the uterine activity, sedation, and fluid balance. If a vaginal examination has not already been done there is an indication for doing it after this lapse of time.

(1) *Artificial rupture of the membranes.*—Often after rupture of the membranes uterine action, previously sluggish, becomes active and the cervix rapidly dilates. In hypertonic inertia the resting tone of the uterus is abnormally high. This is seen in hydramnios. With rupture of the membranes uterine tone is diminished and uterine contractions thereby increased. The tocograph reveals this conclusively.

(2) *Dührssen's incisions.*—This form of treatment has been abandoned by most obstetricians.

(3) *Cæsarean section.*—At any time delivery may have to be rapidly completed on account of maternal or foetal distress. I believe that the lower-segment operation, transperitoneal or extraperitoneal, together with penicillin and chemotherapy, may be life-saving both for mother and baby. Sheehan (1948) has shown how prolonged labour is the greatest single cause of death from shock.

Colonic distension and atony of the bladder, particularly when this organ, even though empty, becomes drawn up towards the umbilicus, are always ominous. When labour is allowed to be so protracted it is best terminated by cæsarean section for in such a case the cervix is usually incompletely dilated. The triad—uterine inertia, atony of the colon and bladder—points to some common ætiological factor of a paralysing nature.

Much harm has resulted from the teaching that delivery must be at all costs *per vaginam* because the membranes have ruptured. Unnecessary vaginal mutilation predisposing as it does to genital infection has resulted from the adoption of this inflexible attitude in obstetric practice. It is safer to do a cæsarean section than a vaginal operation accompanied by much tissue tearing. Abdominal delivery, when the os is only partly dilated, is accompanied with far less trauma than a vaginal associated with multiple incisions of the cervix, vaginal lacerations and an extensive episiotomy.

As yet I have not regretted terminating certain cases of protracted labour by cæsarean section. I wish that for some of the others I had not shown so much zeal for vaginal delivery.

Dr. Joyce Morgan said she had hoped to learn more from the discussion about the condition of the tetanic uterus. In her opinion this condition, formerly known as "rigid cervix", was quite different from uterine inertia. Uterine inertia was a condition of weak, infrequent contractions, whereas in the condition of rigid cervix the contractions were strong and frequent.

This is a rare condition, and she had seen only 26 cases out of a consecutive series of 12,000 deliveries. In all these cases the foetal head was on the perineum, and the undilated cervix was pushed out through the vulva, in front of the advancing head. She had treated the first of these cases with cæsarean section, and the last 20 cases by incision of the cervix. Small incisions only were required, the soft lower segment dilating easily after incisions had been made. They healed remarkably well and gave rise to no trouble. There were no maternal deaths in this series.

Two of these cases were admitted to hospital as emergencies after being in labour for five days, and on admission were found to have dead babies, and a contraction ring, though the cervix was not taken up and admitted only one finger.

Dr. Dick Read: Cases of uterine inertia in the first stage of labour may be divided into three groups which are generally accepted as being concerned with labour, but in my opinion the first group is a pre-labour manifestation and should be recognized as such:

Group 1.—Pre-labour contractions without dilatation of the cervix.

Group 2.—Labour contractions with cervical dilatation.

Group 3.—Inertia of mechanical obstruction with arrested dilatation.

Group 1 is important because it is frequently mistaken for labour. A woman from 37 to 40 weeks pregnant feels uterine contractions which soon become severe and painful. The

pain is described as a tight band *round* the lower abdomen and into the flanks. The contractions are often frequent and colicky, and cause considerable distress; vaginal examination reveals a normal cervix—neither open nor taken up. There is probably little or no contraction of longitudinal fibres.

This pre-labour muscular activity is a psychosomatic manifestation, and arises from exaggerated anticipation and desire for labour to begin. It is almost entirely circular fibre spasm from sympathetic nerve impulses. It can be relieved by sedation: morphia $\frac{1}{4}$ grain is sometimes indicated, but the condition must be explained to the woman in simple terms. After a few hours' rest and sedative she is instructed to get up and walk, maintaining good posture and relaxed carriage. Not infrequently she returns home for some days to await the onset of labour with no recurrence of the colic. The contractions of true labour are described as quite different and entirely free from the pain she experienced previously.

Efforts to stimulate these cases are ineffective and often dangerous. During these attacks the infant is not embarrassed, but the pain and distress of the mother may tempt the attendant to interfere, if the condition is not recognized.

Group 2 is also cortico-thalamic in origin to a large extent. Chemical factors and muscular ineffectiveness are probably secondary and not primary phenomena.

In a state of apprehension and fear, the protective, inhibitory impulses to the circular fibres override the motor fibres of the longitudinal uterine axis. Not only resistance to dilatation occurs, but also weakened motor stimuli. Moreover, the sympathetic nerves supply the muscle walls of the arteries to the uterus and, as Langley and Anderson pointed out, when in action, the volume of blood reaching the muscle tissues is markedly diminished.

Thus, the paucity of nutrition, the inhibition of motor impulses and the resistance of the relatively tonic outlet combine to produce a state of inertia. Complete muscular relaxation, patience and self-control enable labour to proceed. Sleep from time to time is essential, and food in the form of light meals should be given freely. With this treatment, labour will usually terminate within seventy-two to eighty hours in a natural delivery. In the first stage of such a labour, stimulation rarely succeeds, and is to be eschewed. The removal of psychological causal factors allows a progressive although slow cervical dilatation, without exhaustion to the mother or danger to the child. The greatest danger is interference, and should not be resorted to unless clearly indicated by the condition of either the mother or her infant.

Group 3 is an obstetric emergency, and early diagnosis of obstruction to the presenting part is the key to success. The treatment in the first stage is one of three methods: (a) Cæsarean section. (b) Manual or operative dilatation of the cervix and forceps extraction if necessary. (c) To wait for full dilatation and allow delivery or deliver vaginally.

This type of inertia may be dangerous to both mother and child. The infant may suffer from prolonged, frustrated pressure. The mother may become rapidly exhausted and shocked. When diagnosed, the course indicated should be adopted without delay, in spite of apparently weak contractions.

Dr. R. G. Maliphant: Classical uterine inertia is not a common condition and rarely causes practical difficulties. The serious obstetric problem is the irritable uterus commonly seen in association with posterior position of the occiput and in cases of minor disproportion. Uterine action, though vigorous, is inco-ordinate and ineffective, and labour comes to a standstill in the course of the first stage. In my view, cæsarean section has a definite but small place in the management of this condition, and should be reserved for cases in which the cervix has not been well 'taken up'. Usually the cervix is thinned out and manual dilatation followed by forceps extraction is the method of choice. Subsequent confinements in these women take a fairly normal course.

Mr. John Howkins: In the anatomical approach to the problem of the innervation of the uterus we find that the pain centres for the uterus in the cord are situated somewhere between D.11 and D.12, and can be blocked by a local or caudal anæsthetic going to this level and not higher; if the caudal is taken higher, as has happened in one of my cases, above D.6, the centres in the cord which subserve uterine contraction are inhibited, and a strong labour can be converted into a case of primary inertia. A better understanding of the anatomy of the nerve control of uterine contractions in labour might enable one to inhibit spasm, rigidity and lack of polarity in the cervix, without upsetting the power of the detrusor muscle of the uterus.

DISCUSSION ON THE TREATMENT OF SEPTIC ABORTION

Dr. A. Melvin Ramsay: The London County Council Puerperal Sepsis Unit at the North Western Hospital, Hampstead, with which I have been associated since 1937, has been the only Unit of its kind in London since the Isolation Block at Queen Charlotte's closed in 1939. We have therefore had a unique opportunity to study the problems of post-partum and post-abortion infections. The relative incidence of the latter has risen steadily; whereas in 1932 only 16% of our cases were post-abortion, in 1945 the number had risen to 55.9%.

We deal entirely with infected cases and our treatment has therefore tended to be along conservative lines since we feel that intra-uterine manipulation may facilitate spread of infection; indeed, we believe that, with inexperienced or over-enthusiastic operators, it can prove disastrous. No doubt with the advent of penicillin that danger has been considerably modified but that is all the more reason why we should face clearly the lessons that accrue from past experience under less favourable conditions and I certainly very strongly deprecate the attitude that penicillin therapy permits of laxity either in bacteriological investigation or in the application of sound principles of treatment (Kenny, 1945).

The general hospitals deal with the uninfected incomplete abortion daily, and in skilled hands the removal of retained products is a perfectly safe procedure nor can there be any objection to it as a principle of treatment. It is in the case of the infected incomplete abortion that a conservative attitude is defensible even in this penicillin era.

The routine at the North Western Hospital has been to delay vaginal investigation for some hours after admission; careful observation of the general condition and pulse-rate will indicate the presence of an early peritonitis or septicæmia and if either of these is suspected, treatment is at once instituted. Otherwise the patient is given a good night's rest and is then examined in the lithotomy position the following morning. When retained products are present in the cervical canal they are grasped firmly with an ovum forceps and removed. An examining finger may then be passed into the uterus but intra-uterine manipulation is avoided; we are firmly convinced that it is this latter procedure that may prove dangerous in that it breaks down the natural lymphocytic barrier and so tends to cause spread of the infection. If hæmorrhage demands it, however, removal is carried out under intravenous pentothal anaesthesia.

In an analysis of our results for the ten-year period 1937-46, 1,430 cases of post-abortion pyrexia were dealt with; 1,217 of these had infection localized to the uterus and ranged from mild to severe types. In only 97 (8.0%) was removal of retained products under general anaesthesia performed and of these 31 had been done before admission to the Unit. In other words, 92% of these cases recovered without intra-uterine manipulation. We aimed at establishing adequate drainage with Fowler's position and intra-uterine glycerin in certain cases. We found that pyrexia subsided much more rapidly than in the post-partum cases. The average stay in hospital was ten to twelve days. During that time portions of placenta would frequently be passed without hæmorrhage and with no general disturbance; all cases were re-examined before discharge and no patient was allowed to go unless the os was closed and the uterus well involuted. Only in 3 of the 66 cases in which we removed retained products could I find any evidence that we had done so on account of persistence of pyrexia and with subsidence of the same after removal.

In the remaining 213 cases invasive complications of various kinds were present and these may be analysed as follows:

Type of invasive complication	No. of cases	No. of cases with removal under gen. an.	No. of fatal cases	No. of fatal cases with removal under gen. an.
Pelvic infections	130	9	6	1
General peritonitis	13	3	8	2
Septicæmia	54	15	30	11
Metastatic and other infections	16	4	3	1
Total	213	31 (14.5%)	47	15 (31.9%)

Of the 31 cases which had removal under general anaesthesia 22 were done before admission to the Unit; of the 15 in the fatal group 12 were done before admission.

The incidence of removal under general anaesthesia (14.5%) is almost twice that in the uncomplicated group while the rate in the fatal cases (31.9%) is nearly four times as great. One is struck also by the high rate of removal associated with the more severe invasive complications, e.g. 27.8% of the septicæmia cases had removal under general anaesthesia but only 6.9% of the more benign pelvic infections. Among the fatal septicæmia cases the rate of removal was still higher, namely 36.7%. More important still is the fact that at least 19 of the 31 cases had removal performed before the infection became generalized.

pain is described as a tight band *round* the lower abdomen and into the flanks. The contractions are often frequent and colicky, and cause considerable distress; vaginal examination reveals a normal cervix—neither open nor taken up. There is probably little or no contraction of longitudinal fibres.

This pre-labour muscular activity is a psychosomatic manifestation, and arises from exaggerated anticipation and desire for labour to begin. It is almost entirely circular fibre spasm from sympathetic nerve impulses. It can be relieved by sedation: morphia $\frac{1}{4}$ grain is sometimes indicated, but the condition must be explained to the woman in simple terms. After a few hours' rest and sedative she is instructed to get up and walk, maintaining good posture and relaxed carriage. Not infrequently she returns home for some days to await the onset of labour with no recurrence of the colic. The contractions of true labour are described as quite different and entirely free from the pain she experienced previously.

Efforts to stimulate these cases are ineffective and often dangerous. During these attacks the infant is not embarrassed, but the pain and distress of the mother may tempt the attendant to interfere, if the condition is not recognized.

Group 2 is also cortico-thalamic in origin to a large extent. Chemical factors and muscular ineffectiveness are probably secondary and not primary phenomena.

In a state of apprehension and fear, the protective, inhibitory impulses to the circular fibres override the motor fibres of the longitudinal uterine axis. Not only resistance to dilatation occurs, but also weakened motor stimuli. Moreover, the sympathetic nerves supply the muscle walls of the arteries to the uterus and, as Langley and Anderson pointed out, when in action, the volume of blood reaching the muscle tissues is markedly diminished.

Thus, the paucity of nutrition, the inhibition of motor impulses and the resistance of the relatively tonic outlet combine to produce a state of inertia. Complete muscular relaxation, patience and self-control enable labour to proceed. Sleep from time to time is essential, and food in the form of light meals should be given freely. With this treatment, labour will usually terminate within seventy-two to eighty hours in a natural delivery. In the first stage of such a labour, stimulation rarely succeeds, and is to be eschewed. The removal of psychical causal factors allows a progressive although slow cervical dilatation, without exhaustion to the mother or danger to the child. The greatest danger is interference, and should not be resorted to unless clearly indicated by the condition of either the mother or her infant.

Group 3 is an obstetric emergency, and early diagnosis of obstruction to the presenting part is the key to success. The treatment in the first stage is one of three methods: (a) Caesarean section. (b) Manual or operative dilatation of the cervix and forceps extraction if necessary. (c) To wait for full dilatation and allow delivery or deliver vaginally.

This type of inertia may be dangerous to both mother and child. The infant may suffer from prolonged, frustrated pressure. The mother may become rapidly exhausted and shocked. When diagnosed, the course indicated should be adopted without delay, in spite of apparently weak contractions.

Dr. R. G. Maliphant: Classical uterine inertia is not a common condition and rarely causes practical difficulties. The serious obstetric problem is the irritable uterus commonly seen in association with posterior position of the occiput and in cases of minor disproportion. Uterine action, though vigorous, is inco-ordinate and ineffective, and labour comes to a standstill in the course of the first stage. In my view, caesarean section has a definite but small place in the management of this condition, and should be reserved for cases in which the cervix has not been well "taken up". Usually the cervix is thinned out and manual dilatation followed by forceps extraction is the method of choice. Subsequent confinements in these women take a fairly normal course.

Mr. John Howkins: In the anatomical approach to the problem of the innervation of the uterus we find that the pain centres for the uterus in the cord are situated somewhere between D.11 and D.12, and can be blocked by a local or caudal anaesthetic going to this level and not higher; if the caudal is taken higher, as has happened in one of my cases, above D.6, the centres in the cord which subserve uterine contraction are inhibited, and a strong labour can be converted into a case of primary inertia. A better understanding of the anatomy of the nerve control of uterine contractions in labour might enable one to inhibit spasm, rigidity and lack of polarity in the cervix, without upsetting the power of the detrusor muscle of the uterus.

TABLE I

Year	No. of cases	No. extracted	Septic	% Septic	Total deaths
1942	396	160	36	22.5	2
1943	443	443	86	19.4	1
1944	388	153	20	13	2
1945	357	128	17	13.3	3
1946	362	125	10	8	1
1947	371	371	70	18.9	1
Total	2,317	1,380	239	17.3	10

It will be noted that the approximate percentage of septic cases varied from 8 to 22.5%. The total percentage of septic cases among those analysed was 17.3%. The total number of deaths for the period was 10. That is a mortality of 0.43% for the total number of cases, 2,317.

Treatment.—First, immediate surgical intervention, and secondly, a course of chemotherapy followed by intervention. In the cases under review excessive hæmorrhage was considered the only reason for immediate operative interference in the presence of pyrexia. In these cases a digital curettage followed by a flushing douche of dettol was performed. Packing was not carried out routinely but only in cases where the placental débris proved abnormally adherent and separation of this caused a free hæmorrhage which was not controlled by uterine contractions. In all other cases with pyrexia associated with slight bleeding the conservative method was adopted. Chemotherapy was given and when the temperature had been normal for forty-eight hours evacuation of the uterus was performed. Here again a uterine pack was seldom used except to control bleeding. The incidence of packing can be seen in Table II. In the whole series packing was found necessary on eight occasions. In the grossly infected cases where the infection had spread to the tubes or pelvic peritoneum intervention was only undertaken in those cases which continued to bleed. Conservative treatment was adopted in the cases of salpingitis, parametritis or pelvic peritonitis unless a localized pelvic abscess formed and then a posterior colpotomy was done. Pelvic abscess occurred in six cases in the whole series. Spontaneous drainage of the abscess occurred in two cases. In one the abscess had burst spontaneously into the rectum before admission, in the second a foreign body had been pushed through the posterior fornix and the abscess was draining through this opening.

Transfusions.—Only in 25 cases was blood transfusion considered necessary. Hæmorrhage was found not to be a marked feature in septic cases.

Table II gives an analysis of the cases with the method adopted and the complications of the cases.

TABLE II

Year	Septic cases	D & C	Pack	D & C not done	Trans- and para-fusion	Salpingitis and parametritis	Peri-tonitis	Pelvic abscess	Septi-cæmia	Deaths
1942 ..	36	29	0	7	2	1	1	0	2	2
1943 ..	86	71	2	13	7	3	2	3	4	1
1944 ..	20	16	0	4	3	4	1	0	0	2
1945 ..	17	11	1	5	3	0	0	0	0	3
1946 ..	10	8	1	1	4	1	0	1	1	1
1947 ..	70	49	4	17	6	8	2	2	0	1
Total	239	184	8	47	25	17	6	6	7	10

Bacteriology.—Cervical swabs were taken on admission and blood cultures when generalized infection was suspected. The commonest causal organisms were *Bacillus coli* and *Staphylococcus albus*. There were a few cases of infection by hæmolytic streptococci, anaerobic streptococci and *Cl. welchii*.

Chemotherapy.—In the earlier years the sulphonamides were given; latterly penicillin alone or penicillin in conjunction with sulphonamides in grossly infected cases. In gas gangrene infections anti-gas gangrene serum was given.

Deaths.—The causes of the 10 deaths were then fully reviewed by the author, and summarized as follows: Gas gangrene was the cause of death in 4 cases; septicæmia in 2; lacerated uterus (criminal abortion) in 1; acute nephritis 1; bronchopneumonia and septic nephritis 1; and shock 1 (due to insertion of corrosive fluid into the pregnant uterus).

Summary.—239 cases of septic abortion have been considered. These are unselected cases from a total of 2,317 abortions occurring over a period of six years. There were 10

8 of the pelvic infections, 7 of the septicæmia cases and all 4 of the metastatic group had removal carried out before there was any evidence of spread of infection. On the other hand, one of the pelvic group, all 3 of the cases of generalized peritonitis and 4 cases of septicæmia had the removal done after the infection had spread. In the remaining 4 septicæmia cases it was difficult to decide from the records whether spread of infection preceded or followed the removal as the two events appeared to coincide closely.

As the septicæmia group showed the highest percentage of removal under general anæsthesia a fuller analysis was made and this resulted as follows:

Type of organism	No. of cases	No. of cases with removal under gen. an.	No. of fatal cases	No. of fatal cases with removal under gen. an.
<i>Staphylococcus aureus</i>	24	5	10	2
Anaerobic streptococcus	14	7	11	7
<i>Clostridium welchii</i>	8	1	3	—
Hæmolytic streptococcus (Group A3, Group B4, Group G1) ..	8	2	6	2
Total	54	15 (27.8%)	30	11 (36.7%)

This analysis shows that removal of retained products is predominantly associated with the most lethal of the post-abortion group of organisms, namely the anaerobic streptococcus. I may say that in post-partum infections with the same organism there is a very clear connexion with the intra-uterine manipulation entailed in manual removal of adherent placenta.

We have post-mortem records of 46 of the 47 deaths which occurred in this series. In the 32 cases in which no removal had taken place, the records show that no placenta remained in the uterine cavity in 26 and of the remainder only small fragments were found in 5; a spongy mass of what was probably altered placenta was found in the sixth. Retained products which are left in situ are therefore either passed naturally or may to some extent be liquefied and pass in the lochia.

Admittedly the position has been altered by the advent of penicillin since most of the organisms that are responsible for post-abortion infections yield to it whereas sulphonamide therapy in established infections was consistently disappointing. But penicillin has provided us with a powerful reinforcement to Nature's restorative processes and should be used as such and not as an excuse for routine interference. I am certain that caution is needed in dealing with a case of severe spreading infection especially if peritonitis is present. A multipara aged 34 was admitted with acute toxæmia following abortion; well-marked icterus and a very low pulse pressure signified a *welchii* septicæmia which was subsequently confirmed bacteriologically. In addition she had an extensive pelvic peritonitis. I was urged to remove retained products in order to "eliminate the focus of infection". I declined to do so and advised the institution of combined penicillin and sulphonamide therapy first. The following morning I was able to remove a large mass of foul placenta without an anæsthetic. But if that had not been practicable I should have refrained from the administration of a general anæsthetic to a patient so toxic, with a blood-pressure of 80/60 and with such extensive peritonitis.

I trust I have been able to show from this investigation that in cases of infected abortion: (1) The most important principle in treatment is the control of the infection; (2) there is no necessity to carry out a routine removal of retained products under general anæsthesia in every case; (3) removal of retained products under general anæsthesia seldom exercises any beneficial and may indeed exert an adverse effect on the course of the infection.

REFERENCE

KENNY, M. (1945) *J. Obstet. Gynaec.*, 52, 4.

Dr. I. R. Bishop: It seems to me that the crux of the problem in septic abortion is the method of treatment. With this in view I have attempted to carry out an analysis of over two thousand cases of abortion admitted to St. James' Hospital, Balham, during the years 1942-47 inclusive.

The criteria for the diagnosis of septic abortion were similar to those adopted by Stallworthy, namely that an abortion was considered septic when associated with pyrexia for which no other cause was found, with offensive or purulent discharge, or with evidence of pelvic infection. Cases with pyrexia only during the process of abortion were not considered septic. Unfortunately during the war years owing to a shortage of medical and clerical staff the system of filing of the notes has made it impossible to analyse all cases but I have succeeded in extracting over thirteen hundred unselected cases, the distribution of which is shown in Table I.

Dilatation of the os was avoided if possible, retained products were loosened with the gloved finger and removed with ring forceps. Curettage, intra-uterine glycerin, uterine packing, oxytocic drugs and douching were all avoided, and hæmorrhage was controlled by bimanual compression. Dilatation of the os, however, had not been proved to be harmful, and figures quoted showed that no different results were obtained in cases where dilatation of the os was done and where it was avoided.

Types II and III cases were treated conservatively with sulphonamides and penicillin, and appropriate sensitivity and blood concentration tests were done if the response was inadequate. Sulphathiazole up to 80 grammes, and penicillin up to 10,000,000 units, have been found necessary in some cases. A pointing abscess was opened and drained, but posterior colpotomy was only necessary on one occasion. Pelvic masses rising into the abdomen were carefully outlined with a skin pencil, and if they continued to enlarge were also opened. Once the acute phase was over local heat was applied in the form of intrapelvic diathermy, and was continued if necessary for two to three months.

Average length of stay in hospital was 19.9 days, compared with 9.7 days in the case of non-infected abortions.

There was one death from septicæmia, the patient dying shortly after admission to hospital.

An analysis of the associated organisms showed that *B. coli* was most frequently encountered, being present in 30% of cases. Hæmolytic streptococci were only found on 8 occasions, and only 2 of these were identified as belonging to Group A. These infections, however, were nearly all severe, and 3 of them spread outside the uterus. *Cl. welchii* infections occurred twice. Anaerobic streptococci had not been isolated, but had probably been the infecting pathogen in some cases in which no growth had been obtained on culture of the vaginal swabs.

The use of propamidine was advocated particularly for anaerobic infections which were sulphonamide and penicillin resistant. This had been given intravenously in doses of 2 mg. per kilogram of body-weight chiefly in cases of thrombosis and embolism following full-time labour, but the good results obtained justified the use of this aromatic diamidine in treating septic abortions if they were not amenable to other forms of therapy.

Mr. John Stallworthy stated that he wished to re-emphasize the principles laid down in the article which had been published from Oxford in the *B.M.J.* of July 19, 1947, over the signatures of Mr. Corston and himself. In fairness to them both, and in view of some of the criticisms which this paper had evoked, he would like to make it clear that it was not claimed by them that the "interventionist attitude" which they supported was in any way original. They had merely published their experience of the treatment of 600 cases by early evacuation and had analysed their results.

The main concept to be emphasized was that the placental site is a wound and should be treated as such. When it is clean no treatment is required; when it is infected then the sepsis requires treatment; when it is bleeding the hæmorrhage must be stopped. He pointed out that the steady moderate hæmorrhage continuing for days or weeks was in the long run often just as dangerous as the more severe acute hæmorrhage of shorter duration. He claimed that he was not speaking with any great practical knowledge of the subject in so far as the total series of incomplete, inevitable and septic abortions handled in his department since its inception nine years ago was only 803. Of the many cases treated in the years before this accurate records were not available, and as impressions were dangerous his comments were confined entirely to the experience gained from this series of 803. The incidence of septic abortion in this series had been approximately 10% and the total number of septic cases analysed relevant to the discussion was only 85. There were, however, certain factors which should be taken into account on the credit side of the picture. They were that all the cases treated were collected in one hospital and its associated annexes. In the event of subsequent complication occurring there was only one hospital to which they could return so that had mishaps occurred as a result of, or in spite of, treatment, these would have been soon discovered. This point was particularly important when one was defending a line of treatment perhaps more radical than that practised by many. Whatever other criticism could be made it would be irrelevant and unfair to suggest that the subsequent progress of cases when discharged from hospital was not known.

In connexion with the treatment of septic abortion it was well to remember that prevention was better than cure. It had often been said that criminal interference was the usual cause of septic abortion. Whether this was so remained to be proved, but it was undoubtedly a common cause and too frequently took its toll not only of the single young woman in distress, but of the mother harassed by a young family, inadequate housing, lack of assistance and lack of money. In such cases a more liberal guidance on contraception as an aid to family planning would do much to help avert the tragedies so often associated with criminal and septic abortion.

deaths in the whole series from which two may be excluded as not due to sepsis, namely the case of shock and the one of abortion occurring spontaneously in a patient suffering from acute nephritis.

8 cases may therefore be said to have died directly as a result of septic abortion out of a total of 2,317 cases of abortion.

The treatment adopted was evacuation of the uterus only after saturation of the blood with sulphonamides or penicillin. It is felt that the risk of generalized spread of the infection as a sequel to intervention is minimized by this procedure and I think the results will support my claim.

Dr. C. W. F. Burnett: A septic abortion is one in which infection enters the body through the genital tract either before or during the process of abortion or during the subsequent puerperium. It is considered evidence of such infection if the temperature is maintained above 99° F. for twenty-four hours during or within two weeks of an abortion, and is not accounted for by any extraneous lesion, or if there are signs of intra-uterine or peri-uterine infection. Cases are considered as severe if the temperature rises above 100·4° F. (38° C.), and are classified into three types: Type I in which infection is limited to the uterus, vagina or perineum; Type II in which infection involves the pelvic cellular tissues, tubes, pelvic peritoneum or veins, and Type III which is associated with generalized peritonitis or septicaemia. At the West Middlesex County Hospital during 1946 and 1947 there have been treated 1,035 cases of abortion, of which 115 were septic, an incidence of 11·1%. 43% were mild cases and 57% severe. 83·5% were of Type I, 13·1% of Type II, and 3·4% of Type III. Criminal interference was acknowledged in 20·8%, but probably accounted for the majority of cases.

Treatment of a Type I septic abortion can be considered under four headings corresponding to the four basic elements in the treatment of infection.

(1) The inhibition of bacterial growth. Our practice is to use antibiotics and chemotherapy after a high vaginal swab, a blood-count, and a catheter specimen of urine have been taken for diagnostic purposes. A blood culture is asked for if the temperature exceeds 102° F. Sulphatriad is used at present (chosen because of the small risk of urinary crystallization) and is given in an initial dose of 6 grammes, followed by 3 grammes four-hourly. A blood sulphonamide concentration of 10 mg% is aimed at, and initial doses are given parenterally if necessary. A daily fluid intake of 6 pints is maintained, and the urine is kept alkaline. Penicillin is given in an initial dose of 100,000 units, followed by 40,000 units four-hourly if the organism is found to be penicillin sensitive.

(2) Prevention of bacterial spread. This is effected by reducing interference to a minimum, and no instrumentation is permitted beyond the removal of any chorionic material that is felt lying in the cervical canal. This is a valuable procedure because it often stops haemorrhage, and spares the patient the necessity of a blood transfusion or immediate transfer to the theatre for evacuation of the uterus. Oxytocic drugs are not given for fear of disseminating infection by muscular contractions of the uterus, and douching is avoided for fear of mechanical spread. Fowler's position is still employed.

(3) Maintenance of the defensive reaction of the body by good diet and nursing. Anæmia is corrected by fersolate or matched rhesus-negative blood transfusions. The temperature sometimes falls dramatically after a transfusion.

(4) Removal of the cause of the infection. This is the most debatable part of the treatment, because surgical evacuation of the uterus is diametrically opposed to the principle of no instrumentation, and may therefore cause spread of infection. If hæmorrhage is severe, the question is answered, and the uterus must be emptied. This was done in 16 cases and no intensification of sepsis or spread beyond the uterus occurred. In the absence of hæmorrhage it is best to wait for the infection to be brought under control before proceeding to evacuation of the uterus. This was done in 39 cases, of which 34 had a mild convalescence after operation and 5 a stormy one, and spread outside the uterus occurred in 2 cases.

However, one should not wait very long for this to occur. If the temperature and pulse do not fall after waiting for twenty-four to thirty-six hours with sulphonamide and penicillin therapy, evacuation should then be performed, provided there is no extra-uterine spread. This was done in 20 cases, of which post-operatively 11 were mild and 9 severe and 3 subsequently spread outside the uterus. These figures appear to justify a policy of waiting and giving the infection an opportunity of being controlled before proceeding to evacuation.

When the infection has been brought under control evacuation can be done after waiting for twenty-four hours; figures quoted showed that results were the same as those achieved by waiting for longer periods up to a week.

Evacuation was found to be necessary in 65% of cases. It was performed under thiopentone anaesthesia, and was preceded by an injection of 250,000 units of penicillin.

Dilatation of the os was avoided if possible, retained products were loosened with the gloved finger and removed with ring forceps. Curettage, intra-uterine glycerin, uterine packing, oxytocic drugs and douching were all avoided, and hæmorrhage was controlled by bimanual compression. Dilatation of the os, however, had not been proved to be harmful, and figures quoted showed that no different results were obtained in cases where dilatation of the os was done and where it was avoided.

Types II and III cases were treated conservatively with sulphonamides and penicillin, and appropriate sensitivity and blood concentration tests were done if the response was inadequate. Sulphathiazole up to 80 grammes, and penicillin up to 10,000,000 units, have been found necessary in some cases. A pointing abscess was opened and drained, but posterior colpotomy was only necessary on one occasion. Pelvic masses rising into the abdomen were carefully outlined with a skin pencil, and if they continued to enlarge were also opened. Once the acute phase was over local heat was applied in the form of intrapelvic diathermy, and was continued if necessary for two to three months.

Average length of stay in hospital was 19.9 days, compared with 9.7 days in the case of non-infected abortions.

There was one death from septicæmia, the patient dying shortly after admission to hospital.

An analysis of the associated organisms showed that *B. coli* was most frequently encountered, being present in 30% of cases. Hæmolytic streptococci were only found on 8 occasions, and only 2 of these were identified as belonging to Group A. These infections, however, were nearly all severe, and 3 of them spread outside the uterus. *Cl. welchii* infections occurred twice. Anaerobic streptococci had not been isolated, but had probably been the infecting pathogen in some cases in which no growth had been obtained on culture of the vaginal swabs.

The use of propamidine was advocated particularly for anaerobic infections which were sulphonamide and penicillin resistant. This had been given intravenously in doses of 2 mg. per kilogram of body-weight chiefly in cases of thrombosis and embolism following full-time labour, but the good results obtained justified the use of this aromatic diamidine in treating septic abortions if they were not amenable to other forms of therapy.

Mr. John Stallworthy stated that he wished to re-emphasize the principles laid down in the article which had been published from Oxford in the *B.M.J.* of July 19, 1947, over the signatures of Mr. Corston and himself. In fairness to them both, and in view of some of the criticisms which this paper had evoked, he would like to make it clear that it was not claimed by them that the "interventionist attitude" which they supported was in any way original. They had merely published their experience of the treatment of 600 cases by early evacuation and had analysed their results.

The main concept to be emphasized was that the placental site is a wound and should be treated as such. When it is clean no treatment is required; when it is infected then the sepsis requires treatment; when it is bleeding the hæmorrhage must be stopped. He pointed out that the steady moderate hæmorrhage continuing for days or weeks was in the long run often just as dangerous as the more severe acute hæmorrhage of shorter duration. He claimed that he was not speaking with any great practical knowledge of the subject in so far as the total series of incomplete, inevitable and septic abortions handled in his department since its inception nine years ago was only 803. Of the many cases treated in the years before this accurate records were not available, and as impressions were dangerous his comments were confined entirely to the experience gained from this series of 803. The incidence of septic abortion in this series had been approximately 10% and the total number of septic cases analysed relevant to the discussion was only 85. There were, however, certain factors which should be taken into account on the credit side of the picture. They were that all the cases treated were collected in one hospital and its associated annexes. In the event of subsequent complication occurring there was only one hospital to which they could return so that had mishaps occurred as a result of, or in spite of, treatment, these would have been soon discovered. This point was particularly important when one was defending a line of treatment perhaps more radical than that practised by many. Whatever other criticism could be made it would be irrelevant and unfair to suggest that the subsequent progress of cases when discharged from hospital was not known.

In connexion with the treatment of septic abortion it was well to remember that prevention was better than cure. It had often been said that criminal interference was the usual cause of septic abortion. Whether this was so remained to be proved, but it was undoubtedly a common cause and too frequently took its toll not only of the single young woman in distress, but of the mother harassed by a young family, inadequate housing, lack of assistance and lack of money. In such cases a more liberal guidance on contraception as an aid to family planning would do much to help avert the tragedies so often associated with criminal and septic abortion.

There was, however, another aspect of the subject to which emphasis was given. Just as criminal interference was a cause of many septic abortions so lack of interference, which some day may be regarded as criminal, was responsible for many more. Too often the woman who was admitted with a septic abortion had incompletely aborted spontaneously several days or even several weeks before and had been permitted to continue with retained placental tissue. This was done either because of an unjustifiable optimism that all would be well if left to Nature, or because of a deliberate policy on the part of a medical attendant who had been taught that interference in such cases was dangerous. In over 800 consecutive cases treated at the Radcliffe Infirmary, Oxford, by evacuation there had been only one death and that was in a woman who had aborted incompletely one month previously. There had been daily hæmorrhage subsequently and it was not until one month later when her hæmoglobin was 22% and she was moribund with a terminal *Cl. welchii* septicæmia that she was admitted too late to hospital where she died within twenty-four hours. This case gave further emphasis to the plea for early treatment of incomplete abortion, and it was claimed that by this early treatment many septic abortions would be avoided.

Reference was then made to the technique of therapeutic abortion. It was stated that there could surely be no scope in these days for the two-stage evacuation of the uterus either by tents, bags, plugging or other methods. If it was necessary to terminate a pregnancy on therapeutic grounds, then it should be done as a clean surgical procedure either by dilatation and evacuation in the early stages, or by hysterotomy, vaginal or abdominal, if the uterus was too big for the first manœuvre.

In the treatment of septic abortion once the condition was established it should be remembered that sepsis and anæmia were frequently associated. In the Oxford series blood transfusion was administered in 14% of all abortions treated, but in 25% of the septic group. The two enemies of recovery were hæmorrhage and sepsis. In combating the hæmorrhage two things were essential, to replace any severe blood loss by prompt transfusion and to prevent further hæmorrhage by emptying the uterus. The suggestion made by Dr. Gibbon Fitzgibbon in his paper recently published in the *Journal of Obstetrics and Gynecology of the British Empire* that this order of treatment was incorrect and that the uterus should be emptied first was challenged. It was pointed out that no surgeon would perform a gastrectomy for a bleeding ulcer until he had restored the patient to such a condition as to make operation reasonable and safe. In the same way it seemed that the patient was being submitted to an unnecessary risk if, when she was already exsanguinated, the risk of further blood loss was accepted, when by waiting a very short time her condition could be made safe for operation. These were the principles on which the treatment carried out at Oxford had been based.

Reference was then made to *Cl. welchii* infection and to the terrible clinical picture it presented; the cold clammy cyanosed skin, the almost imperceptible pulse with a blood-pressure which could not be recorded, post-mortem lividity present while the heart was still beating, as if to mock the attempts made to defeat the angel of death, suppression of urine or at the most a few drops of a port-wine colour, but even with the imminence of death the eyes still bright and the mind fully conscious.

It was pointed out that the diabetic patient was rather more liable to infection with gas-forming organisms than the non-diabetic, and reference was made to the work of Kemp who had recorded gas production in the diabetic with both actinomycotic and anaerobic streptococcal infection. A slide was shown illustrating infection of the brain of a foetus *in utero* by gas-forming organisms in a diabetic woman not in labour and herself apparently free from infection. It was pointed out that the only possible source of infection of the foetus was by the maternal blood-stream.

The speaker concluded with a brief summary of the clinical treatment and ultimate recovery of a young woman who within eighteen hours of the induction of a criminal abortion was in an apparently moribund condition with a combined *Cl. welchii* and *B. coli* septicæmia. The uterus was evacuated on the fifth day after admission. The importance of giving eucortin to combat the profound effect of Clostridium toxin on the adrenals was emphasized.

DISCUSSION ON NUTRITION AND RESISTANCE TO INFECTION

Dr. P. G. H. Gell (*National Institute for Medical Research, Hampstead*): It is usually taken for granted that among human populations mass starvation is an important factor in the genesis of epidemics of infectious disease. Historically, this is by no means easy to demonstrate; so often, famine is only the most painful feature of a situation which includes overcrowding, breakdown of normal sanitary measures, mass movements of population, and general demoralization. All these factors are likely to play a part. However these—except of course the last, the psychological imponderable—do no more than intensify the exposure of the population to infection. Once exposed, the individual may also (as a result of starvation) have a lowered resistance.

Resistance again can be divided up into its various stages. For instance, the non-specific power of the skin to clean itself of pathogens appears to be due, in part at least, to the secretion of fatty acids in the sebum. In cases of malnutrition, at any rate in many of those I saw in Germany, the dryness and flakiness of the skin is extremely striking; one would expect that its self-sterilizing power would have been reduced and in fact German practitioners complained of the excess of superficial skin lesions they were meeting.

Too little is known about these non-specific, surface defences of the human body, especially in generalized pathological conditions such as starvation. Not very much more is known about the effect of starvation on the internal "trigger"-defences, cellular and humoral, that is, those mechanisms which operate before specific immunity has been established—normal antibodies, phagocytosis and so on. However, there is one type of defence one would expect to be affected, namely, the production of antibodies; because this entails the synthesis or at least the adaptation of serum proteins on a fairly large scale, and of course one of the presenting signs of malnutrition is a lowered serum protein.

Indeed the system of priorities which the body follows when it is undernourished is of extreme interest. Everything goes to show that the defence mechanisms are pretty high on the list. One has only to think of the danger of a failure to segregate the bacteria in our own intestines to see why this is so. Nevertheless, a certain amount of experimental work has been done on animals, which goes to show that malnutrition, and especially protein starvation, depress their antibody-response to vaccines and their resistance to infection.

Now protein undernutrition is clearly the best condition in which to investigate depression of antibody-response, because the metabolism of antibody protein is practically bound to be affected.

The situation in Germany in 1946, where the experiments I shall describe were carried out, presented the more usual picture of general caloric undernutrition—a reasonably balanced diet, but not enough of it. This is, however, the characteristic post-war situation, and when Professor R. A. McCance organized a unit, under the aegis of the Medical Research Council, to investigate the physiology of undernutrition, the opportunity was taken to investigate antibody production.

The work was carried out in Wuppertal, a fair-sized industrial township on the edge of the Ruhr, in the summer of 1946. The basic ration at this time was 1,000 calories: in urban districts, severe undernourishment was widespread, though not sufficiently serious to cause clinical symptoms in most of the population. This was the situation in which we set out to investigate antibody production. This is, of course, by no means the only measurable immune mechanism, but it is the simplest to measure accurately.

In order to observe both the primary and the secondary response, it was essential to choose a vaccine to which the subjects could have no pre-formed, latent immunity; and after trials, a somewhat bizarre mixture was chosen, consisting of tobacco mosaic virus, avian red cells, and a saprophytic vibrio. The latter failed to produce demonstrable agglutinins in any of the test or control subjects, and results with it have not been included. Each subject received two injections at an interval of three weeks: the sera were sampled before the first injection and weekly thereafter for five weeks.

The test subjects were divided into two groups: (1) 32 patients selected from those sent up to Barmen Municipal Hospital as cases of malnutrition, and (2) 25 prisoners from the civil gaol at Siegburg, also showing symptoms of undernourishment on clinical examination.

Sixteen normal subjects, mostly British troops, were used as controls.

The results, which are summarized in Table I, were not wholly satisfactory, largely owing to the very low titres attained throughout; this may have been due to the nature of the anti-

TABLE I.—PERCENTAGES OF SERA GIVING AGGLUTINATION AT A DILUTION OF 1:8 OR MORE

Group	versus Fowl Red Cells			versus Tobacco Mosaic Virus		
	Before injection	During three weeks after first injection	During two weeks after second injection	Before injection	During three weeks after first injection	During two weeks after second injection
Siegburg (prisoners)	8.0	60.0	60.0	0.0	52.0	48.0
Barmen (patients)	6.3	37.5	65.5	0.0	53.1	31.3
Normal controls	0.0	81.3	87.5	0.0	93.7	93.7

gens, the time interval of injection, or other conditions. No agglutination was recorded with either antigen at a titre higher than 1/64. The data have been subjected to statistical analysis, and the superiority of control to test groups in all periods, shown to be significant. But is this due to undernourishment?

There is one factor in which the test and control groups differ considerably, namely, the age distribution; the average age of the controls was in the twenties, of the test subjects in the forties. However, the correlation between age and antibody production within the groups is statistically not significant (Barmen 0.129, Siegburg 0.104, Controls 0.185), and in the absence of immunological evidence that in adults age affects antibody response, this factor seems unlikely to have affected the results. One can, I think, reject the racial difference; the social distress resulting from defeat in war is the essential factor in which the groups differ. Of this social set-up, undernutrition is one factor which has been shown to affect antibody production in animals; therefore, I think it is safe to assume that the difference in antibody production between the groups is mainly due to undernutrition.

Finally, what bearing do these results have upon the problem of epidemic disease? I would draw attention to three points: (1) The extremely severe degree of undernutrition from which the test subjects were suffering—severe enough to render active life impossible; and (2) in spite of this, the comparatively small differences between these literally famished subjects and the controls, in first-class condition; (3) the significant fact that there actually has not been any widespread epidemic disease in Germany since the end of the war. These points taken together suggest that undernutrition does not play as large a part in widespread epidemics as is generally supposed.

This does not dispose of famine as a medical problem, of course, any more than it disposes of it as a human problem; in such signs as a high mortality rate and high incidence of tuberculosis the effect of undernutrition is evident; while the appallingly demoralizing effects of famine constitute a grave psychological problem on their own.

(This work will be published in detail in a Report to the Medical Research Council from the M.R.C. Unit working in Wuppertal.)

Mr. Herbert Parry (Animal Health Trust, Newmarket): Part I^a. *Some of the Variables Involved.*—Any real appraisal of the role played by nutrition in resistance to infection must consider at least four aspects, namely, the host, the nutritional status of the host, the character of the infection and the nature of the resistance, each aspect comprising many variables. The definition of these variables, at first qualitatively and later quantitatively, is essential in dealing with this complicated subject. It is proposed, therefore, to consider in a tentative way some of these variables.

(1) *The host.*—An adequate discussion of this would involve all those factors determining the host's internal environment, cellular and systemic, in which the parasite comes to live. This is obviously impossible, but certain gross determinants, genetic and developmental, must be stressed. The importance of differences between species, and also between different genetic strains within a single breed of a species can be enormous. Results obtained on one strain of a species are not necessarily valid for any other. Hence, it is essential in experimental studies to standardize the genetic constitution of the host animal as far as possible by using highly inbred strains of a given species.

Developmental variation may be equally important, since the age and stage of growth of the animal often plays a decisive role in the outcome of infections. It is well known that young adolescent mice of less than 20 grammes body-weight are much less susceptible to many neurotropic viruses than are older and heavier animals. This phenomenon has been termed "maturation resistance" (Sabin, 1941). If the growth of young mice be retarded by

^aPart II of this paper, *Studies of Total Infections*, will be published in full elsewhere.

restricting food intake or by feeding a diet inadequate for normal growth, such animals retain their "maturation resistance" and are less susceptible to certain experimental infections, although of an age normally fully susceptible. Such lowered susceptibility has been interpreted on occasion as due to some deficiency in the diet. In such instances, unless a control group on a complete diet—but with the food intake precisely similar to that of the deficiency group—be also infected, it is equally possible that the results are due to a continuing "maturation resistance".

(2) *The nutritional situation.*—The nutrition of the host can in part be defined by stating the current consumption of the known nutrients, namely the calories, protein, fat, carbohydrate, the various minerals and accessory dietary factors, but this is not enough. To define the *total nutritional situation* it is necessary to know the previous intake and the reserves of any nutrient, as well as the acuteness or the chronicity of a deficiency of any individual nutrient. Experimentally, individual deficiency states can be produced. In the field, a simple deficiency of one nutrient almost never occurs. We are dealing with adequate and inadequate diets composed of many combinations of individual nutrients in supra-optimal, optimal and sub-optimal amounts, the effects of different nutrients operating in diverse ways, and being often mutually exclusive. Under such conditions it becomes wellnigh impossible to assess the role of nutrition. The experimental approach using diets of highly purified constituents with individual food consumption records and the paired feeding technique seems to offer the only chance of unravelling the tangled skein of conflicting clinical experience. The successful maintenance of animals on such purified diets has made it possible to standardize the nutritional situation.

(3) *The infection.*—Parasitic organisms show so many variations in their effects on a host that to standardize the infection is as important as standardizing the nutritional situation. Detailed consideration of this matter is beyond the scope of this discussion, but suffice it to say that the number of parasitic organisms, their virulence and general biological characteristics within the host, as well as their portal of entry and any auxiliary aids to their establishment, such as trauma or stasis in the alimentary tract, must be defined as precisely as possible.

(4) *Resistance.*—The term resistance has been used to denote so many and various effects that it is increasingly necessary to define what is meant by the term. For the present purpose it is convenient to separate resistance into three levels: first, resistance to the invasion of the parasite through the skin or mucous membranes, *invasion resistance*; second, resistance to the multiplication of the parasite and the accumulation of its pharmacologically active metabolic products in the blood and tissue fluids, i.e. *systemic resistance*; and third, *organ resistance*, resistance to the passage of parasites from the systemic circulation into an organ, and resistance within the organ to any deleterious effects due to the parasites' presence.

(a) *Invasion resistance:* In the main, interest here has been focused on the role of vitamin A in the maintenance of the integrity of ectodermal structures and thereby the resistance of these structures to invasion by parasites. A voluminous and somewhat uncritical literature has grown up which purports to show that the vitamin-A-deficient animal (and man) is more prone to infections of the skin, eyes and alimentary tract. Much of this evidence is in need of a critical reappraisal in the light of recent knowledge.

The role of nutrition in parasitism of the alimentary tract is more clear-cut. There is experimental evidence that a nicotinic-acid-deficient diet will allow the intestinal multiplication and subsequent transmucosal invasion of *Salmonella* in pigs (Chick *et al.*, 1938a, b; Davis *et al.*, 1940) and probably in mice (Watson *et al.*, 1938), while Waisman and Elvehjem (1943) report a diarrhoeic syndrome due to *Shigella paradysenteriae* in monkeys fed a diet deficient in folic acid, and which was controlled by feeding small quantities of folic-acid concentrates.

While the precise reason why these deficient diets should provide conditions suitable for the accumulation of parasites in the bowel is obscure, another group of disorders, the enterotoxæmias of herbivores, are definitely related to the development of local alimentary stasis due to dietary causes, which thereby provide conditions suitable for the rapid multiplication and toxin formation by *Clostridium welchii* (Roberts, 1938).

(b) *Systemic resistance:* Resistance at this level involves many fundamental mechanisms, several of which are to be discussed by other speakers. They will, therefore, only be mentioned very briefly. It is convenient to do so under two heads, first, antiparasitic agencies and, secondly, sensitivity to parasitic toxins.

Antiparasitic agencies include antibody formation, which can be modified by diet; phagocytosis which is limited in the leucopenia of folic-acid deficiency in the monkey; and the absence of metabolites essential for the parasite, a situation more likely to occur in theory than in practice, since the host's requirements are likely to be, in most instances, as critical as those of the parasite.

Sensitivity to toxins, i.e. the size of the mean pharmacological dose, is known to be

influenced in some cases by the nutrition of the host. Thus, diphtheria toxin probably combines with ascorbic acid, and a relative ascorbic-acid deficiency may occur in diphtheria, even when the ascorbic-acid intake is adequate for normal circumstances (King and Menten, 1935; Menten and King, 1935). It is suggested that a very high ascorbic-acid intake may reduce the sensitivity of the host to this toxin, and it is probable that the optimal ascorbic-acid requirement is increased in all fevers. Mice fed on certain mixed diets without skim milk are less resistant to the intraperitoneal inoculation of *Salmonella typhi murium* toxin (Watson, 1937).

(c) *Organ resistance*: The resistance of an organ to an infection embraces two distinct phenomena, *organ entry resistance* and *organ damage resistance*. The former is the resistance to the entry of the parasites, i.e. to their localization, in an organ, the classical example of which is the mechanism of the blood-brain barrier. *Organ damage resistance* may be defined as those factors which limit the damage done to the functional efficiency of the organ by the presence of the invaders or of their metabolic products. Little is known of the factors involved, other than the general mechanisms discussed under systemic resistance, but presumably complex cellular enzyme systems are also involved. There are suggestions of this in the work of the Wisconsin school on the role of thiamine in determining the development of functional defects of the nervous system due to some neurotropic viruses (see Rasmussen *et al.*, 1944).

(d) *Criteria of resistance*: So many criteria of increased resistance have been employed, including lengthening of the incubation period, lessened severity of the local signs of organ damage, the shortening of the duration of clinical signs, reduced numbers of deaths, reduced numbers of viable organisms as determined by laboratory tests, more rapidly produced or higher antibody titres, and others. Many of these criteria embrace different aspects of invasion, systemic and organ resistance. Unless due regard be paid to these differences when selecting criteria there seems little chance that the true role of nutrition in resistance to infections will be elucidated. Of the many possible criteria, one of the simplest is the development of functional defects in the central nervous system following infections with the neurotropic viruses, which involves in particular organ resistance. In the hands of Clark and his colleagues (see Rasmussen *et al.*, 1944) the retardation of the development of paralysis of the hind-limbs in infected animals has proved a valuable quantitative criterion of resistance.

Dr. Z. A. Leitner: When bacteria or their products enter the body they are gradually removed by the "clearing mechanism" consisting mainly of the wandering cells of the reticulo-endothelial system [5]. Soon afterwards "shedding" of fragments of the superficial cytoplasm layers of these cells occurs and coincides with the appearance of antibodies [11] and with an increase of gamma globulins [6]. The cells forming the gamma globulins appear to be sensitized and they seem to synthesize antibody globulin more rapidly than normal cells when exogenous protein gains access to them [11]. Moreover, in dogs depleted of proteins by inadequate diet or plasmaphoresis, the replenishment of antibody globulin depends on supply of dietary protein after exhaustion of the "reserve bank" of intracellular proteins [12]. Sufficient amount of dietary protein seems, therefore, to be as essential for adequate synthesis of antibodies as their proper absorption from the intestine and the conversion of amino-acids into plasma proteins in the liver. Interference with any of these functions may lead to hypoproteinaemia and infections (e.g. in liver cirrhosis).

Avitaminoses, especially those due to vitamin-A, -C and -D deficiency, are also said to reduce natural resistance. Conflicting views about the relationship of vitamin deficiency to infection appear to be due partially to the varying definition of the deficiency itself [7]. Whilst in cases of vitamin deficiency administration of the missing vitamin may help to restore normal resistance, such vitamin therapy does not increase resistance or immunity in normal persons.

Vitamin-A deficiency causes an atrophy of the epithelial surfaces followed by keratinizing metaplasia and a lowered local resistance. This may partly explain a variety of infections in

animals [3] and also in children [2]. A more satisfactory explanation cannot be advanced yet as to the mechanism of decreased general resistance in vitamin-A deficiency; it does not appear to be due to diminished antibody production though vitamin-A deficiency may interfere with the efficient action of natural antibodies, especially in children [1, 4].

Results of an investigation carried out by the author with Drs. Jacobs, Moore, Sharman and Thornton during the last four years on the relation of vitamin A to certain infections were briefly discussed. Tables demonstrating the carotene and vitamin-A values in normal persons [8, 9] and, as a comparison, the considerably lowered vitamin-A values in patients suffering from pleurisy, pneumonia and especially from rheumatic fever were shown [10]. A guarded indication for prognosis was put forward on account of some observations made during the recovery period in rheumatism. The curves presented seemed to indicate that there was no recurrence after the first attack in patients with high vitamin-A level; other cases with apparently complete clinical recovery and normal E.S.R. but with low blood vitamin-A level had repeated relapses during the observation period. A warning against generalization from these preliminary observations was added and the hope expressed that they might contribute to further elucidation of the relationship of certain nutritional factors to infection, particularly in rheumatic fever.

Dr. J. W. Howie said that fifteen months ago the Rowett Research Institute, Aberdeen, adopted work on nutrition and resistance to infection as part of its programme, and he spoke for a team of workers now engaged on the subject. Observations were being made on the immunity responses of calorie- and protein-deficient ewes. The immunity response was not always a true index of capacity to resist infection; therefore it seemed most useful to study the type of antibody best established as a factor in resistance. For this reason, with the collaboration of Mrs. I. Batty, of the Wellcome Research Laboratories, the antibody under investigation was *Clostridium welchii* β antitoxin. It was possible to say only that at this stage of the work and with the particular scheme of immunization employed the calorie- and protein-deficient ewes had produced more antitoxin than the well-fed control animals; details of the experiment would not be reported until it was complete, and the final picture might be quite different.

Mice on different diets were also being tested by noting the survival rates after infection with a variety of agents including Salmonella, louping-ill virus, and tubercle bacilli. A colony of white Swiss mice had been established and in consequence of rigid precautions it had been kept free from spontaneous Salmonella infection for one year. Thus it was possible to design experiments in which the test and control animals were alike in age, sex, and heredity and differed only in their diets. It was well known, and had been confirmed, that some diets influenced resistance to infection only in the next generation. In one experiment raising the proportion of casein in the diet without increasing the calories had resulted in greater resistance in young male mice to Salmonella infection by mouth, but the resistance of young female mice had not been influenced by the same procedure. The experimental diet was unsatisfactory for reproduction and rearing and the experiment was being repeated with what he hoped might prove a more satisfactory diet.

Other experiments were also in progress at the Institute on the effect of a protein-rich supplement on the worm burdens of ewes and their lambs; on antibody production in pyridoxin-deficient rats; and on nutritional and other environmental factors likely to influence the resistance of young pigs to infection.

The problems were attractive, as might be judged by the numerous publications on the subject, but clear answers to most questions about nutrition and resistance to infection were still lacking, as Schneider (1946) had demonstrated.

Sir Percival Hartley said that, in his studies of the factors affecting antibody production, prominence had been given to the effect of nutrition. Experiments had been carried out on guinea-pigs and included the three main phases of their immunization history—the response to the primary and secondary stimulus, respectively, and the quiescent period between these events. The antigens used were diphtheria toxoid and alum-precipitated toxoid, the diphtheria antitoxin produced was precisely measured, and the state of nutrition varied by adjusting the amount of cabbage fed daily to the animals.

Response to the primary stimulus was markedly affected by diet. Fifteen guinea-pigs given an adequate diet grew well, all survived and gave an excellent antibody response; an exactly similar group given mangolds in place of cabbage did not grow, four of them died, and the survivors gave a poor antibody response [1]. By using groups of 50 guinea-pigs it was shown that animals given 50 grammes of cabbage daily produced a significantly larger amount of antitoxin than those given 20 grammes daily. When 13 immunized guinea-pigs were deprived of cabbage for twenty-one days, there was no change in the antitoxin level in 5 and a slight decline occurred in 8. The cabbage-free diet being continued, these 13 guinea-pigs were given the same dose of antigen as 12 similarly immunized guinea-pigs which had been maintained constantly on an adequate diet. Of the diet-restricted group 5 died on or before the fifth day following the injection of antigen, all of these showing, at post-mortem, characteristic symptoms of undernutrition; but each of the remaining 8 showed a rise in antitoxin titre although it was small compared with that produced by the adequately fed control group. This severe and prolonged deprivation of cabbage was the only condition which affected, significantly, the response to the secondary stimulus; if the restriction was continued for one week only no decline in response occurred [2]. Neither exposure to cold, intercurrent infection persisting throughout the period of the secondary response, a continued condition of tetanus, produced by the injection of a sublethal dose of tetanus toxin and maintained during the whole period of the secondary response, nor intravenous injections of Indian ink made any significant difference to the response to the secondary stimulus. In all the experiments the antigens had been quantitatively investigated before use and, as the charts showed, the doses injected were sufficiently small to permit of the submaximal effects produced being quantitatively estimated and compared.

DISCUSSION ON SWINE ERYSIPELAS INFECTION (*ERYSIPELOTHRIX RHUSIOPATHIÆ*) IN MAN AND ANIMALS

Dr. Mary Barber: *Erysipelothrix infection in man.*—The bacillus of swine erysipelas is either pathogenic or saprophytic throughout the animal kingdom. It can survive in dead matter of animal or plant origin for a very long time and is extremely resistant to salting or putrefaction. Compared with swine, man is relatively immune to infection with this organism. Three types of infection have, however, been described in man, cutaneous, intestinal and generalized; the first type, referred to as erysipeloid of Rosenbach being by far the most common.

ERYSIPELOID OF ROSENBACH

Fox gave what is probably the first description of a single case of this condition in the *British Medical Journal* in 1870. In 1873, Baker, in the *St. Bartholomew's Hospital Reports*, gave an interesting study of 16 cases of a similar condition, which he called erythema serpens. He observed that there was usually a history of injury a few days to a week before the onset; in 6 of his cases the condition followed a scratch by a bone or a cut while handling meat or rabbit skins and one followed a dog bite. He stated that the disease spread leaving "one portion sound as it involves another". The site of injury never showed any signs of infection. The erythema itself never suppurated and there was no inflammation of veins or lymphatics. The prognosis was always favourable, all cases clearing up in two to six weeks.

The classical studies of Rosenbach (1884 *et seq.*) not only established the disease as a clinical entity but proved its causal relationship with swine erysipelas. His description of the skin lesions has not been improved upon. In 1887 he described them as erysipelas-like, slowly progressive, sharply defined, slightly elevated, dark, violaceous, almost livid red zones. He observed, as Baker had done, that the central area of redness faded as the disease extended peripherally. In this same paper he describes the organism which he isolated from a skin biopsy of one patient. He said it was larger than a staphylococcus and in older cultures became a mass of branching threads. He injected a pure culture of it into his own arm and

produced a typical erysipeloid lesion. In a paper in 1909 he compared organisms isolated respectively from swine erysipelas, mouse sepsis and erysipeloid lesions in man. He found them serologically and "toxically" similar, but thought they were distinct morphologically and culturally. Felsenthal in 1893 also recovered an organism from skin biopsies of 3 out of 4 patients with erysipeloid and noted its resemblance to the causal organism of swine erysipelas.

Epidemiology.—The condition is met fairly frequently in any large skin clinic, but as a rule the diagnosis is not confirmed bacteriologically. Most of the cases are cooks, kitchen workers, butchers or people who handle fish, and they occur most frequently between the months of May and September. Klauder (1938) analysed the source of infection in 100 cases. In all, contact with dead animal matter could be traced; in 58, who were abattoir workers, the infection was from swine and in 16 it was from fish.

Clinical features.—The incubation period is in most cases one to five days. The disease is confined almost exclusively to the hand, starting in most cases at the site of the puncture wound and rarely progresses above the wrist. A few cases, where the lesion was on the soles of the feet, face or neck, have been recorded. The patient complains of a sensation of burning, pricking, itching and pain; occasionally the pain is severe, it may radiate up the arm. The surface of the erythematous areas remains smooth, no papules, vesicles or other lesions appear. The most distinctive features are the purplish-red colour and the well-defined margin. Another characteristic sign is that the central area of redness fades as the disease spreads peripherally.

Lymphangitis and glandular enlargement are rare and suppuration has never been recorded. In most cases fever and constitutional symptoms are slight or absent. The lesions disappear spontaneously in from five days to about six weeks, without desquamation. Recurrences, however, are not infrequent.

Diagnosis.—The clinical picture is characteristic and the diagnosis often rests on this alone. Bacteriological confirmation is difficult. It is usually only possible to isolate the organism if an actual biopsy of skin is taken and even then it is not always easy. Of 7 cases admitted to Hammersmith Hospital in the summer of 1945, skin biopsies were cultured from all, but from five only was the organism isolated (see Barber, Nellen and Zoob, 1946). In this localized form of the disease no detectable agglutinins to *E. rhusiopathiæ* appear in the patient's blood stream. Biberstein (1933) described an intracutaneous test using filtrates from cultures of *E. rhusiopathiæ*. He claimed that filtrates from ten-day-old cultures gave 88% of positive results in 17 cases of active erysipeloid; 5% of 60 normal people, however, also gave a positive result.

Treatment.—The assessment of treatment in a disease which is naturally self-limited is difficult. Prior to the introduction of modern chemotherapeutic drugs serum was the usual method and it was claimed to be beneficial. The effect of sulphonamide compounds is disputed. Klauder and Rule (1944) stated that these drugs had no effect on erysipeloid lesions in man and they showed that they had little or no effect on experimental infection of mice with *E. rhusiopathiæ*. Schoch and Shelmire (1940) and Kulchar and Rosenberg (1941) on the other hand claim that sulphonamide therapy has a curative effect on erysipeloid eruptions. Few cases treated with penicillin have so far been recorded, but Heilman and Herrell (1944) have shown that this compound is curative in experimental infection in mice. I myself have observed 1 case treated with penicillin and the effect was dramatic (Barber, Nellen and Zoob, 1946).

Histology.—The histological appearance is not characteristic. Düttmann (1921) has demonstrated that the organisms are usually in the deep part of the pars reticularis of the corium. He therefore points out the necessity for excising deeply for bacteriological studies.

SEPTICÆMIA AND ENDOCARDITIS

Blood-stream infection with *E. rhusiopathiæ* in man is rare. A few cases have however been recorded. Gunther in 1912 reported 2 cases occurring in veterinarians accidentally inoculated with a culture, but these cases were not studied bacteriologically. Prausnitz in 1921 described a child of 10 with a clinical picture of septicæmia and endocarditis from whom *E. rhusiopathiæ* was grown from the blood but no post-mortem examination was performed. The first case of Erysipelothrix infection leading to endocarditis proved bacteriologically and at post mortem was described by Russell and Lamb (1940). There were no skin lesions; the heart was enlarged and there was a systolic thrill and murmur at the base. *E. rhusiopathiæ* was isolated from the blood on six occasions. The patient died a month after admission to hospital in spite of treatment with sulphanilamide. Post mortem the heart was nearly twice normal size, there were three small pinkish-yellow granular firmly adherent vegetations on the anterior cusp of the mitral valve, and the aortic cusps, only two in number, were largely replaced by fungating, friable vegetations.

Klauder *et al.* (1943) reported the condition in a butcher with a history that five months previously his left thumb had been lacerated with a meat bone. This was followed in three days by extensive acute inflammation of the thumb, so severe that one physician recommended amputation. However, complete recovery eventually took place and he returned to work two months after the injury and worked regularly until two months later he felt weak and sick and retired to bed. At this time he had fever and a purpuric eruption. A month later he was admitted to hospital, where he died six months after the original injury in spite of full doses of sulphathiazole.

Blood-count revealed a normochromic anæmia. *E. rhusiopathiæ* was isolated from the blood on three occasions. Post mortem a friable vegetation $\frac{1}{4}$ in. in diameter was present on one aortic cusp.

Infection via alimentary tract.—One case has been reported by Fiessinger and Brouet (1934) in whom infection followed the ingestion of salt pork.

Mr. A. W. Gledhill (*Institute of Animal Pathology, University of Cambridge*): *Erysipelothrix rhusiopathiæ* was identified as the causative organism of swine erysipelas by Löffler in 1885. Losses from the disease have perhaps been most heavy in the Continent of Europe. In Britain it is prevalent in East Anglia where on some farms it would be almost impossible to raise pigs without recourse to vaccination and treatment with immune serum; yet in some other parts of Britain it is quite uncommon.

Erysipelothrix rhusiopathiæ occurs fairly commonly in birds of most species usually causing sporadic deaths, although quite extensive outbreaks among birds have been attributed to it. The organism is also a common cause of arthritis in lambs (Poels, 1913; Christiansen, 1919; Cornell and Glover, 1925), and endocarditis in horses (Paterson and Heatley, 1938).

Formerly, the pig was regarded as being the natural host of *E. rhusiopathiæ*, swine erysipelas and human erysipeloid being supposed to result exclusively from direct or indirect contact with affected pigs. Evidence has, however, accumulated to show that *E. rhusiopathiæ* can live as a harmless saprophyte. The organism has been recovered from the slime of fish, from houseflies and from putrefying matter (Heilman and Herrell, 1944). It can live saprophically in the intestines and tonsils of pigs and this is no doubt true of other species of animals. Six strains of high virulence were recovered from the tonsils of 50 pigs (Bramm, 1937). On other occasions workers have failed to recover the organism from normal pigs (Huytra and Marek, 1920). This difference probably depends upon the locality to which the pigs belonged. Probably this accounts for the fact that in districts where the disease occurs the sera of animals having no history of clinical infection often contain both agglutinins and antibodies capable of protecting mice passively against infection with *E. rhusiopathiæ*. I have observed a rise and fall of agglutinins in sera from horses over a period of several months. Furthermore, three sera from a batch of five similar normal pigs bred at the Institute of Animal Pathology, Cambridge, protected mice against lethal infection with *E. rhusiopathiæ*. Of the two remaining sera, one lengthened the life of the test mice a little, while the other had no effect at all. It was also observed that the serum and precolostrum of a cow had agglutinating titres of 1:40 and 1:160 respectively and that the precolostrum protected mice. If it can be assumed that specific antibodies are concerned with these agglutination and mouse protection results, it would seem that in areas where the disease occurs subclinical infections are common. The active immunity engendered by these perhaps explains the difficulty in producing swine erysipelas by injecting pigs with virulent cultures. Pigs between the ages of 3 months and 1 year are most susceptible. No doubt sucking pigs receive protective anti-

bodies from the sow, whilst pigs over a year of age may have usually acquired sufficient active immunity to resist infection. But the existence of a low-grade active immunity makes it difficult to understand how the majority of young weaned pigs in such districts can become highly susceptible to natural infection, usually in the hot summer months. Whether the emergence of enzootic swine erysipelas is due to a lowered resistance in the pig population or to a sudden rise in virulence of the organism is not known. The virulence of strains of *E. rhusiopathiae* is certainly an unstable entity which can often be raised experimentally.

Three forms of swine erysipelas are recognized in pigs, the mild form characterized by urticaria, the acute septicæmic form and the chronic form, characterized by vegetative endocarditis. It is generally supposed that the acute disease is a septicæmia and that the mild and chronic diseases are preceded by a transient septicæmia before localization of the organisms in the skin, the joints or the endocardium. It was, however, suggested by some early workers that *in vivo* *E. rhusiopathiae* produces an extra-cellular toxin. Thus, the acute disease would be essentially a general toxæmia whilst the urticaria and endocarditis of mild and chronic erysipelas would be due to invasion of the affected tissues by organisms. This view received some support by the observation that after cutaneous inoculation pigs sometimes become fatally affected with symptoms of erysipelas although the bacilli are found only at the point of inoculation and in its immediate vicinity (Hutyra and Marek, 1920). Moreover, "Voges and Schutz (1898) showed that after inoculation with the second Pasteurian vaccine, and after simultaneous injection of antiserum and living virus (sero-vaccination), the blood of pigs was teeming with bacilli, which, nevertheless, caused no visible disturbance in the pigs; Prettnner (1906) found that passively immunized mice harboured virulent infection in their tissues for twenty-four hours to three days after inoculation of culture" (M.R.C. System of Bacteriology, 1931). I have observed that mice, passively protected against the immediate effects of several thousand lethal doses of virulent culture, will often succumb to acute infection several weeks later, especially if subjected to strain. These observations support the view that immune serum acts by neutralizing the toxic effect of *Erysipelothrix* organisms rather than by promoting their destruction. This would seem to imply that the organisms produce a neutralizable toxin *in vivo*. The hypothesis that such a toxin is produced might explain why an organism sensitive to about 0.1 unit of penicillin per ml. yet requires 1,000 units per mouse per day to achieve 95% protection (Heilman and Herrell, 1944; Woodbine, 1946, 1947). This raises the question of curative treatment.

Treatment.—Immune serum in liberal doses has a curative action upon the acute disease in pigs. In man it is also alleged to have a curative action but not infrequently it appears to produce a type of serum sickness more incapacitating than erysipeloid itself. In birds, it has not consistently produced good results (Vianello, 1938; Graham, Levine and Hester, 1939). As curative agents the sulphonamides are not of value (Woodbine, 1946). As already stated, the organism is sensitive to penicillin *in vitro*. To a less extent it is also sensitive to streptomycin. In man a number of instances of the success of penicillin therapy have been published. Upon the hypothesis that the acute fatal infection of mice and pigs is due to a toxin, one might expect greater success in the case of man in whom acute general symptoms are not a regular feature of the disease. Similarly in pigs one might perhaps expect poor results from penicillin therapy in the acute form while the chronic form might be more amenable to treatment. I have not seen any reports of the use of penicillin in pigs. Indeed, it would be difficult to arrange an adequate trial bearing in mind that the disease has not been produced experimentally with any regularity and that pigs affected with the natural disease are treated with immune serum. In the case of the chronic type, the diagnosis is generally established with certainty only post mortem.

Prevention.—The usual method of prophylactic immunization is by inoculating subcutaneously viable culture and immune serum followed by culture alone a week or so later. Satisfactory results are obtained by this method. It does, however, present disadvantages. In the first place, hyperimmune horse serum is expensive and difficult to produce in sufficient quantities to meet the needs of some countries, in particular the Central European countries. Secondly, there are the dangers accruing to the use of fully virulent viable viruses as immunizing agents.

To avoid the use of hyperimmune serum, attenuated viable cultures have been used, e.g. the rabbit-passaged material elaborated by Pasteur. It does not appear to me that the hope of producing a more stable attenuated culture is very well founded. Recently, I obtained from Mr. T. M. Doyle of the Ministry of Agriculture Laboratory, Weybridge, a strain capable of immunizing mice without producing symptoms in them. After subculturing this strain in series daily in 10% pig serum broth and in glucose broth for about a fortnight, the former culture inoculated intraperitoneally was capable of making mice ill. By culturing from the sick mice into the same medium and repeating the operation, the third and fourth mouse passage killed mice in two to three days. The culture was then maintained in pig

serum broth and in due course its virulence determined. It was now capable of killing mice at high dilution although it took longer to kill than would a really virulent culture. It was also shown *in vitro* that the treatment had induced a power in the culture not possessed at first. As shown elsewhere smooth strains of *Erysipelothrix rhusiopathiae* produce an antigenic component when grown in serum media which is not produced in the absence of serum (Gledhill, 1947). This was demonstrated by absorbing with organisms grown in serum-free media an immune rabbit serum produced against the same strain grown in serum media. At first such an absorbed serum did not agglutinate suspensions grown in serum media of the strain in question. However, after the strain had become capable of killing mice it was agglutinated by the absorbed serum at a dilution of 1 : 160, the titre of the absorbed serum with the homologous strain. One can easily imagine natural conditions in which could occur a similar rise in virulence of an avirulent strain as that described here.

The ideal method of immunization is clearly by means of inactivated organisms or by antigenic substances derived from them. Heat-killed cultures are valueless for this purpose. Moreover, it has been shown that merthiolate-killed organisms grown in media not containing serum do not produce immune sera in rabbits (Gledhill, 1945). However, organisms grown in media containing horse serum and similarly killed do produce immune sera in rabbits. To determine experimentally whether such a vaccine would immunize pigs presents the difficulty that pigs are not generally susceptible to artificial infection. In collaboration with Mr. J. A. J. Venn of the Institute of Animal Pathology, Cambridge, I have sought to determine the degree to which vaccines raise the immune bodies in pigs' sera by estimating their capacity to protect mice against infection. As a standard to be attained by vaccines, we have taken the power to protect mice of the sera of pigs immunized with viable culture by the recognized method. Killed organisms grown in serum broth inoculated subcutaneously produced no response, while intravenously the response was insufficient. It has since been found that the cell-free serum broth in which the organism has grown for eighteen to twenty hours is antigenic and the use of this would seem to promise more success in pigs, especially if the fowl is used as the source of serum in the medium (Table I).

TABLE I.—AGENTS PRODUCING IMMUNE BODIES IN SERA OF PIGS

Pig No.	Agent used for immunizing pig	Route of inoculation	Doses injected ml.	Dose of serum given to mice ml.	No. of mice which died
1	Viable culture	s/c	1.0, 1.0	0.1	5/10
2	Supernatant of centrifuged horse serum broth culture	i/v	5, 10, 20, 20	0.1	4/6
3	Supernatant of centrifuged fowl serum broth culture	i/v	2, 4, 6, 6	0.1	1/6
3	Before immunization. None	—	—	0.3	6/6

Infecting dose : 100,000 virulent bacilli given intraperitoneally 24 hours after serum.

Traub (1947) and also Dinter and Bakos (1948) have shown to be present in culture media an antigen capable of immunizing pigs against swine erysipelas. Our observations indicate that the antigen free in the medium resembles that produced on the organism by growth in serum media in the following particulars: (1) Both are produced only in the presence of serum in the medium. (2) Both are thermolabile, being destroyed by heating to 55° C. for thirty minutes. (3) A serum produced in the rabbit against the antigen free in the medium was much reduced in efficacy for protecting mice by absorption with organisms.

Section of Epidemiology and State Medicine

President—W. S. C. COPEMAN, O.B.E., F.R.C.P.

[January 5, 1948]

A Statistical Analysis of Geriatric Care

By L. COSIN, F.R.C.S.

PUBLIC Health and State Medicine, having concerned themselves with the prevention of many of the epidemic causes of death during the last hundred years, must now turn to the situation produced by the success of such a policy.

I shall not mention many figures to indicate the size of the problem except to point out that the number of people of pensionable age will exceed 9,000,000 in twenty years' time; in 1946 the number was 6½ million. The average expectation of life at birth to-day is about 62 in men and 67 in women, while the average morbidity of people over the age of 60 is at least five times that of the population of all ages. Faced with an increasing shortage of nurses and the great increase in the number of elderly invalids, a breakdown in our hospital system is likely unless the problem about to be discussed is solved. Before considering a solution, however, we must ascertain the amount of nursing attention required for the average elderly patient who becomes hospitalized. Although there must be many other correlated factors influencing the hospital stay of ageing patients, the chief are: (1) Type of case admitted. (2) Efficiency of medical and surgical treatment. (3) Amount of rehabilitation provided. (4) Amount of treatment, before admission, which may depend upon the length of the waiting list.

The length of the waiting list is dependent upon the following factors: (1) The size of the hospital. (2) The number of available beds for this type of patient. (3) The varying scarcity of nursing staffs. (4) The size of the aged population in the locality. (5) The patient's social position, which largely determines his ability, or inability, to obtain suitable socio-medical attention, although this is becoming less absolute in its application. (6) The attitude of most voluntary and many municipal hospitals to this type of patient.

Dependent upon these factors are the deplorably late admissions in the natural history of the disease, which may have an effect in shortening hospital stay by an increased death-rate, and the failure of many aged patients to gain admission at all. The use of antibiotics, chemotherapy and cardiac diuretics will also tend to increase the length of hospital stay.

The only figure available for average length of stay of elderly sick appears to be that of 260 days for 1938 quoted by Dr. J. Cohen in the Working Party's Report on the Nursing Profession. Using this figure as a standard of comparison, which is probably still true in many institutions, we can examine some figures from the Orsett Lodge Hospital in the Essex County Council's Social Welfare and Hospital Service. The reopening of the hospital on 7.11.44 for civilian patients after war closure permitted us to survey the results of geriatric rehabilitation over the following twenty-six months until 10.1.47 when the reduction of the nursing staff to 26 determined the closure of 60 beds in two wards.

An active attempt was made to diagnose, classify and treat this neglected type of patient as fully as possible. During the first part of the period under review, treatment was based on routine medicine, surgery and physiotherapy. Our medical and surgical care was producing gratifying results in the diminution of the death-rate but the failure at first to rehabilitate as many elderly patients as possible produced its own bottleneck.

SOURCES OF PATIENTS

During the period under survey—November 1944 to January 1947—Orsett Lodge Hospital, a Social Welfare Institution in a South Essex industrial area, drew its elderly patients from:

- (1) The 23 old people left of the patients not evacuated.
- (2) The return of 91 elderly people in November 1944 and 97 more in March 1945, some 50 of whom were originally from other hospitals.

I think it has been a frequent experience that old patients evacuated during the war were too often allowed to become bedfast instead of being kept ambulant. This may have been due to the nursing and other shortages; however, the rehabilitation of the bulk of these patients, some three-quarters of whom were bedfast, became an important problem.

- (3) The elderly people admitted from the local area, very often after a long period on the waiting list.

(4) The victims of senile confusional states admitted because of the inability of the local mental hospitals to admit all patients of this type.

- (5) Elderly patients from the East London metropolitan area of Barking, Ilford, Romford and Dagenham.

(6) Elderly patients from that part of the north bank of the Thames stretching from East London to Canvey Island, about 35 miles.

serum broth and in due course its virulence determined. It was now capable of killing mice at high dilution although it took longer to kill than would a really virulent culture. It was also shown *in vitro* that the treatment had induced a power in the culture not possessed at first. As shown elsewhere smooth strains of *Erysipelothrix rhusiopathiae* produce an antigenic component when grown in serum media which is not produced in the absence of serum (Gledhill, 1947). This was demonstrated by absorbing with organisms grown in serum-free media an immune rabbit serum produced against the same strain grown in serum media. At first such an absorbed serum did not agglutinate suspensions grown in serum media of the strain in question. However, after the strain had become capable of killing mice it was agglutinated by the absorbed serum at a dilution of 1:160, the titre of the absorbed serum with the homologous strain. One can easily imagine natural conditions in which could occur a similar rise in virulence of an avirulent strain as that described here.

The ideal method of immunization is clearly by means of inactivated organisms or by antigenic substances derived from them. Heat-killed cultures are valueless for this purpose. Moreover, it has been shown that merthiolate-killed organisms grown in media not containing serum do not produce immune sera in rabbits (Gledhill, 1945). However, organisms grown in media containing horse serum and similarly killed do produce immune sera in rabbits. To determine experimentally whether such a vaccine would immunize pigs presents the difficulty that pigs are not generally susceptible to artificial infection. In collaboration with Mr. J. A. J. Venn of the Institute of Animal Pathology, Cambridge, I have sought to determine the degree to which vaccines raise the immune bodies in pigs' sera by estimating their capacity to protect mice against infection. As a standard to be attained by vaccines, we have taken the power to protect mice of the sera of pigs immunized with viable culture by the recognized method. Killed organisms grown in serum broth inoculated subcutaneously produced no response, while intravenously the response was insufficient. It has since been found that the cell-free serum broth in which the organism has grown for eighteen to twenty hours is antigenic and the use of this would seem to promise more success in pigs, especially if the fowl is used as the source of serum in the medium (Table I).

TABLE I.—AGENTS PRODUCING IMMUNE BODIES IN SERA OF PIGS

ANALYSIS OF DEATHS—M. 170, W. 126

Treatment period			Treatment period		
1-7 days	M. 51 W. 26	} 77	91-180 days	M. 16 W. 19	} 35
8-30 days	M. 38 W. 36		181-365 days	M. 7 W. 14	
31-90 days	M. 37 W. 28	} 65	Over one year	M. 21 W. 3	} 24
Total	296			

I will return, after completing the analysis of patients in hospital on 10.1.47, to the problem of the long-stay patient.

TABLE IIA.—ANALYSIS OF RESIDENTS 10.1.47

Active Treatment or Bedfast M. 30, W. 29.

Duration of Treatment			Duration of Treatment		
1-7 days	M. 2 W. 1	} 3	91-180 days	M. 3 W. 2	} 5
8-30 days	M. 2 W. 3		181-365 days	M. 4 W. 4	
31-90 days	M. 6 W. 5	} 11	Over one year	M. 13 W. 14	} 27
Total	59 (8%)			

On 10.1.47 there were 59 patients in bed, of whom 35 can be considered as permanently bedfast, roughly 4% of the total; to this, however, must be added 45 long-term patients who had died after a longer hospital bedfast stay than six months. The total of 80, or about 10% then, is a fair estimate of the problem of nursing the long-stay permanently bedfast cases. The 1947 figures, which were card-indexed and very accurately surveyed by Mr. W. H. Leak, the County Statistical Officer, show that under 10% were permanently bedfast (i.e. over six months).

TABLE IIB.—ANALYSIS OF RESIDENTS 10.1.47

Long-Stay Annexe Residents M. 65, W. 42.

1-7 days	M. 0 W. 0	} 0	91-180 days	M. 3 W. 5	} 8
8-30 days	M. 0 W. 5		181-365 days	M. 16 W. 5	
31-90 days	M. 5 W. 3	} 8	Over one year	M. 41 W. 24	} 65
Total	107 (14%)			

The long-stay annexe residents are rehabilitated patients who are either capable of looking after themselves without any assistance (long-stay annexe for the ambulant) or are in need of extra physical help (long-stay annexe for the frail ambulant). The common feature, however, is the fact that there is no need for a full-time nursing service which would be essential if the patients were bedfast in acute geriatric wards or in a long-stay annexe for the permanently bedfast.

The lengths of stay (Table IIB) comprise both the period in the acute geriatric wards and the long-stay annexes. The mean figure of 51.6 days before discharge could reasonably be used as an index of length of stay in the acute geriatric ward before transfer to the long-stay annexes.

LONG-STAY CASES

Pursuing the problem of the long-stay cases, I have followed up the 166 patients who were in hospital on 10.1.47 to 31.12.47 (Tables III and IV).

TABLE III.—ANALYSIS OF ADMISSIONS BEFORE 10.1.47 MADE ON 31.12.47

	Men	Women	Total
Discharged ..	11	7	18
Transfers ..	2	2	4
Deaths ..	26	18	44
Long-stay annexes	50	31	81
Bed ..	4	15	19

166

TABLE IV.—DISCHARGES DURING 1947

Length of stay	Women	Men	
0-30 ..	—	—	} 11
31-90 ..	5	4	
91-180 ..	—	5	
181-365 ..	—	1	
Over one year	2	1	

Total 18

The number of deaths (44) (Table V) is very interesting because, first they take the total death-rate for the period 7.11.44 to 31.12.47 up to $296 \div 44 = 340$ or 43%, and secondly I have been able to divide them into two categories. 16 of the deaths occurred in patients who had been permanently bedfast over six months for the whole period of hospital stay—that is up to three years, but the new factor of 20 or over half of the long-term deaths occurred in geriatric wards after residence in long-stay annexes. It appears that a large proportion of patients in long-stay annexes for reasons of physical infirmity or social need will have only a short final illness.

(7) Some subjects of surgical emergencies of all ages, including the elderly, from a similar area.

(8) Transfers from other hospitals because of a hopeless prognosis.

The total number of admissions of patients over the age of 60 for this period of twenty-six months amounted to about 780, while the number of patients under that age amounted to about 650, excluding maternity patients. About 200 of the 780 cases were already of the long-stay hospital type admitted during the first part of the period.

RESULTS OF TREATMENT

As much of the analysis was carried out after the end of the period it was not possible to card-index all admissions, as has been done in 1947, but a separate sheet of each month's admissions was prepared for each sex, showing name, age, date of admission and one column each for the date of discharge, death or transfer. A final column was provided to indicate length of stay. In all cases the length of stay has been assumed to be the period of bedfast days.

I have referred to the fact that the analysis was carried out in retrospect and it has not been possible to attain 100% accuracy. This is reflected in the admissions, combined with those ageing patients resident before November 7, 1944, amounting to three less than the combined figure for deaths, discharges, transfers and residents on January 10, 1947. As several patients were readmitted, sometimes on more than one occasion, this probably accounts for an error which is less than 0.4% (Table I).

Results of Treatment of Patients Over 60 Admitted Between 7.11.44 and 10.1.47				Admissions 7.11.44 to 10.1.47		Average Duration of Stay in Days of Elderly Patients Admitted Between 7.11.44 and 10.1.47		
						Death	Discharge	Transfer
Transferred	M. 16 } W. 19 }	35	4%	M. 438 } W. 317 }	755	Men 92.2	53.6	270.1
Discharged	M. 177 } W. 107 }	284	37%	Resident 6.11.44		Women 82.2	49.2	206.9
Died	M. 170 } W. 126 }	296	38%	M. 20 } W. 3 }	23	87.6	51.6	235.0
Resident 10.1.47	M. 95 } W. 71 }	166	21%			I am grateful to Dr. Cohen, of the Cabinet Office, for providing the statistical figures of average length of stay.		

The transfers amount to 35 or 4% of the total. The usual causes of transference are lunacy certification, and those patients needing radium, deep X-ray or thoracic surgery, which are not available at this hospital. On this occasion, however, 15 from a long-stay annexe were accounted for by their transfer in July 1946 to another Essex County Council hospital as a result of the war evacuation, which explains the high average length of stay. Probably a 2% transfer rate is more usual.

The total number of patients discharged amounts to 284 or 37% of the total. This represents a large batch of rehabilitated elderly patients: others will be found in an analysis of patients in hospital on 10.1.47 (Table II A and B) as 107 (14% of the total) were in long-stay annexes for ambulant or frail ambulant cases. This brings the total number of rehabilitated elderly up to 51%.

ANALYSIS OF DISCHARGES—M. 177, W. 107

Treatment period			Treatment period		
1-7 days	M. 32 } W. 12 }	44	91-180 days	M. 18 } W. 7 }	25
8-30 days	M. 56 } W. 41 }	97	181-365 days	M. 10 } W. 6 }	16
31-90 days	M. 58 } W. 40 }	98	Over one year	M. 3 } W. 1 }	4
Total	..	284			

It will be seen that 239 or over 80% of these patients were discharged under three months, while another 41 were discharged in under one year.

As this analysis was over a two-year period it is reasonable to assume that recovery should be completed in less than one year, but only six months should be required for about 90% of the cases.

On turning to the deaths it was found that there were 296 out of 781, making a percentage of 38. The interesting fact here is that 73% or nearly three-quarters of the deaths occurred in less than three months after admission to hospital, that 85% of the deaths had taken place in less than six months, while 8% of them, or 3% of the total admissions, took place between twelve and twenty-six months.

Old Age in General Practice

By TREVOR H. HOWELL, M.R.C.P.

WITH old age to-day, the emphasis has been laid on the new geriatric units or departments which, it is hoped, will solve the problem of the aged chronic sick. But every physician and surgeon who is treating elderly patients echoes the same cry: "Why didn't we get these sooner." The geriatric departments of the present resemble an Army base hospital. The damage has been done before the patients get there. All of them have gone down the line, from hospital to hospital, before they come to the place in which serious treatment begins. In many parts of the country there is no special unit which welcomes these patients.

Time and again in general practice and at the Royal Hospital, Chelsea, I saw some relatively trivial illness develop into a major disease when neglected. It is only necessary to compare the incidence of diseases with the cause of death to become aware of this.

Provisional diagnosis
4,622 pensioners

Causes of death
250,000 over 65 (1942)

Bronchitis	14%	Cardiac disease	30%
Senility	12%	Cerebral vascular	14%
Myocardial degeneration, &c. ..	10%	Cancer	12%
Influenza	8%	Bronchitis	7%
Minor surgical	8%	Old age	6%
Dyspepsia	8%		

As for the terms "senility" and "debility", I have kept a record of the ultimate diagnosis of cases with these provisional diagnoses. About a third of these had some cancer, usually in the large gut; another third developed some form of cardiovascular failure; many of the remainder had hidden sepsis, usually in the urinary system. Another group of cases are those who die with a terminal bronchopneumonia. The original disease in these patients may be a true chronic bronchitis, a long-standing arthritis, a fractured femur, or some past cerebral vascular lesion. In the same way, many cases dying with gangrene of the leg have begun with some small injury or infection of the foot. This was neglected at first, then treated too vigorously too late, by putting the patient to bed which altered the state of his circulation and allowed the gangrene to spread.

In old age, prevention is better than cure, as well as being easier. An experienced general practitioner will often ward off serious illness in his old patients time after time, in a way undreamt of by younger men. When I was at the Royal Hospital, Chelsea, I found it possible to reduce the death-rate by admitting pensioners to the infirmary at an early stage of their illness. The patients found in the chronic hospitals are usually those who have been mismanaged in the early stages of their illness. Such conditions as chronic arthritis, hemiplegia and incontinence of urine can be treated successfully in the majority of patients. Most old folk labelled "senility" can be physically rehabilitated to a considerable extent.

If these things can be achieved in a few hospitals which have a geriatric unit, they can be carried on throughout the country. I have treated chronic arthritis and hemiplegic patients successfully in general practice.

A dozen geriatric out-patient clinics in this country would save blocks of hospital beds, and release hundreds of nurses for other work.

The Evolution of a Geriatric Unit from a Public Assistance Institution, 1935-1947

By MARJORY WARREN, M.R.C.S., L.R.C.P.

SINCE 1935—that is during the last twelve years—a geriatric unit has been evolved from a public assistance institution. This unit is now an integral part of the general public health hospital and carries 200 beds. The hospital itself had been appropriated by the local authority (M.C.C.) about five and a half years previously. It is as yet far from ideal, but I venture to suggest that it registers a reasonable step in the right direction.

In June 1935 we took over 874 chronic patients (including 16 maternity and about 144 mental observation patients). I propose to exclude these maternity and mental beds as they are outside the main issue, and in any case other than reducing the number of the mental beds, little has been developed in these wards so far—this left 714 chronic patients, more than half of whom were bedridden, many for long periods of time.

We had the good fortune to be able to transfer, after medical examination, 200 inmates—including elderly and destitute able-bodied workers—to another institution provided for them. This left us with 514.

TABLE V.—DEATHS IN 1947 FOLLOWING ADMISSION BEFORE 10.1.47

Bedfast days	Permanently bedfast	From long-stay annexe	
0- 30 days	M. 0 } W. 0 } 0	M. 4 } W. 5 } 9	
31- 90 days	M. 4 } W. 1 } 5	M. 1 } W. 3 } 4	
91-180 days	M. 1 } W. 2 } 3	M. 3 } W. 0 } 3	
181-365 days	M. 0 } W. 0 } 0	M. 4 } W. 0 } 4	
1- 2 years	M. 4 } W. 3 } 7	M. 0 } W. 0 } 0	
Over 2 years	M. 6 } W. 3 } 9	M. 0 } W. 0 } 0	
Total	24	20	

The third column shows the number of patients with their period of residence in bedfast wards before and after residence in the long-stay annexes, the average being 94 days.

The bedfast cases had diminished from 35 to 19, due to deaths and, in two cases, rehabilitation which had been delayed into the third year of the analysis because our very able physiotherapist, Miss Nunn, could not deal with such a problem alone in a short time. Rehabilitation is now rendered easier by the training of four physiotherapy aides who considerably ease the work of the department. The reduction in the number of occupants of the long-stay annexes from 107 to 81 should be noted, although their places have been filled by the 1947 admissions.

Criticism of the results obtained must be conditioned by the proportion of direct admissions, the length of the waiting-list and the proportion of cases transferred from other hospitals or other hospital departments.

As the period of rehabilitation must depend upon how much previous neglect had ensued before effective treatment commenced, these figures may not be exactly comparable with other geriatric departments. It is essential, however, to ascertain the necessary length of bedfast stay for the elderly patient who has not been adequately treated for more than a period of weeks. We hope this will be a natural consequence of the establishment of geriatric departments. Although the results are not yet completed the twelve months' period of examination ending 31.12.47 more than confirms the earlier results; the advantage of the latter period has been the rehabilitation rate equalling the rate of admission without a large number of bedfast patients awaiting rehabilitation in hospital. In the latter half of 1947 the waiting period before admission had been reduced to a few days.

Table VI shows the time spent in the long-stay annexes by the 20 patients mentioned in Table V, before readmission to the acute geriatric ward where death occurred.

TABLE VI.—DURATION IN LONG-STAY ANNEXE (AVERAGE 1 YEAR 315 DAYS)

0- 90 days	M. 0 } W. 0 } 0	181-365 days	M. 3 } W. 0 } 3	Over 2 years	M. 5 } W. 7 } 12
91-180 days	M. 3 } W. 1 } 4	1-2 years	M. 1 } W. 0 } 1		

Summary.—An analysis was made of 781 admissions over 60 years of age during a recent twenty-six-month period to the Geriatric Wards of Orsett Lodge Hospital in the Essex County Council Social Welfare Department. This showed that of the 296 (38%) deaths, 85% had occurred after less than six months' hospital stay, while 8% (3% of the total admissions) occurred more than twelve months later.

The total number of rehabilitated patients (51% of the admissions) consisted of 284 (37%) who were discharged and 107 (14%) who were in Long-Stay Annexes for the Frail Ambulant, or Ambulant, residents at the end of the twenty-six-month period (10.1.47).

Of the 166 residents on 10.1.47 (21%) the bed patients were found to consist of 35 (4.5%) permanently bedfast (over six months) and 24 (3%) who were receiving active treatment. The long-stay permanently bedfast cases are considered to be 10% of the total admissions.

A further analysis of the 166 residents on 10.1.47, one year later, showed that the permanently bedfast long-stay cases had fallen to 2.5% while the 44 deaths fell into three distinct categories:

- (i) The short-term deaths (8).
- (ii) The long-term deaths after more than twelve months' permanent bedfastness (16).
- (iii) Deaths following a period of residence in the long-stay annexes for ambulant or frail ambulant cases (20).

The average length of stay of discharged patients was found to be 51.6 days and the average length of stay of the patients who died was found to be 87.6 days.

To Dr. Bullough, the County Medical Officer of Health for Essex, to Professor Greenwood, the Consulting Statistician, and to Mr. W. H. Leak, the County Statistical Officer, I express my gratitude for much helpful criticism and advice.

DISCUSSION ON RENAL CIRCULATION

Dr. Joseph Trueta and Dr. A. E. Barclay [*Summary*]: In March 1941 cases described as "crush syndrome" were recorded. Following severe crushing, usually of the lower limbs, apparent recovery was followed by progressive impairment of renal function and death from renal failure about a week after the injury had been sustained. This clinical picture was soon established as more cases were recorded. Various theories were put forward to account for the sequence of events, none of which seemed to give a satisfactory explanation. Trueta and Barnes, working in Oxford, thought that the explanation might perhaps lie in some reflex effect on the vascular supply of the kidney, causing ischæmia. They therefore produced a condition in rabbits resembling crush injury by the application of a tourniquet to one of the hind-limbs for a period of four and a half hours. It was found after removal of the tourniquet and on injecting radiopaque material into the abdominal aorta that there was active spasm of the femoral artery which might persist for days. The circulation below this zone of spasm was greatly restricted, if not actually suppressed. Further, it was noted that a similar type of spasm frequently occurred in the femoral artery of the uninjured leg and sometimes extended up the internal iliac arteries. Was it possible that a similar type of spasm also affected the renal circulation?

Owing to war conditions, it was not possible to continue the work till September 1945 when a team was formed at the Nuffield Institute for Medical Research, Oxford, to follow up clues given by these early experiments. This team consisted of a surgeon (Dr. Trueta), a physiologist (Dr. Franklin), a radiologist (Dr. Barclay) a pathologist (Dr. Daniel), and a graduate assistant (Miss Prichard).

A technique was devised by which a radiopaque substance, thorotrast, was injected through a cannula into the jugular vein. X-ray cinematograph records, which gave accurate timing of the progress of the opaque blood, were made of the vessels of the kidney as the blood passed through them. From these records on control animals, it was shown that the renal artery was visualized in three seconds and the renal vein in six seconds from the time of injection. The field of the X-ray ciné was, however, of limited size, and it was clear that information as to other vessels was needed. X-ray ciné-recording was therefore replaced by taking single large-size films at the critical times of three and six seconds from the time of the injection. These films included virtually the whole animal. It was found that after the tourniquet had been applied definite changes occurred in certain vessels and, in particular, there was definite narrowing of the renal artery and an increase in the size of the renal vein. It was also noted that sometimes the renal vein was already visible when, according to the control, only the renal arteries should have been seen. This suggested a disturbance in the circuit time of the blood through the kidney. To investigate this the X-ray ciné was used to check the times, and it was found that whereas in the normal animal the circuit time from the renal artery to the renal vein was three seconds, in the tourniquet animals it might be reduced to almost a half of this time. This could only be explained on the hypothesis that the blood had not traversed the whole kidney but had taken a short circuit, so arriving in the renal vein more rapidly.

The next stage was to make direct observations by means of laparotomy on animals that had been subjected to a tourniquet on the leg. In these experiments, the surface of the kidney was often found to be very pale and bloodless. The colour of the blood in the renal vessels was also clearly seen and it was noted that there

At this time, not only was there a greater demand for beds for the elderly (for treatment and for custodial care) but there was also a general desire and need to expand all the hospital services. Both these conditions are likely to happen again this year. As a result everybody cast their eyes to the chronic wards and wanted some of the beds—empty of course, for nobody wanted to take over the chronic sick. But they were full and at that time seemed likely to remain so.

The removal of the 200 patients did not, as might be hoped, leave us with 200 empty beds, for the first move in the plan of betterment was to reduce the bed numbers to correct spacing for treating sick patients. This reduction was undertaken gradually during the next two years so that during the whole transition period we were open to admit new patients.

Between June 1935 and March 1936 every one of the 514 patients was fully examined medically and in many instances socially too. In March 1936 our first big move in classification of patients was undertaken.

Three types of patient were removed from the sick geriatric wards: (1) Up and about patients awaiting discharge to relatives or transfer to resident homes; (2) incontinent patients, (3) cot-bed patients.

During the next three years equipment comparable to that on the acute medical wards and special equipment required on geriatric wards was provided. The wards were painted in light colours and generally brightened up. Swing doors replaced the narrow fixed doors. Lighting was improved.

As a direct result the burden of medical work and nursing care was lightened, and gradually a number of very long-stay inmates were improved satisfactorily and in time discharged to their homes.

As an indirect result in 1939 one ward of 45 patients was emptied and handed over to the T.B. Service and it has remained ever since in use for female T.B. patients. One ward of 22 beds was handed over to the skin department and one ward of 18 beds was converted into: (a) Small gymnasium. (b) Second X-ray department.

Progress continued in spite of the difficulties and frustration of war and in the absence of further major improvements. With the quicker turnover of patients, further wards were given to other departments to help in the overall expansion of the hospital.

And so to date I have a compact geriatric unit of 200 beds, and two full-time house physicians appointed. Recently I have been asked to undertake in addition the medical supervision of the 200 patients in the Resident Home (P.A.I.).

We are therefore caring for 200 hospital elderly sick and 200 institutional elderly persons in 400 beds instead of 714 chronic sick and destitute mixed up in wards which required a 24-hour nursing service and gave no opportunity for adequate care or teaching.

Dr. E. L. Sturdee: The three speakers have shown, in their own hospitals, that patients thought to be bedridden can be put on their feet again. Many of the results they are achieving would seem like miracles to the medical staffs of hospitals where similar methods have not been tried.

It looks as though two lines of research are needed. Professor J. B. Duguid, speaking recently at the Professional Nurses and Midwives Conference, stated that old age did not kill, but that there was always some pathological cause of death. Research is needed, therefore, into the difference between the pathological or preventable processes of old age and those that are natural and inevitable.

The second and more easily managed research is into the early symptoms of chronic diseases, and into the methods of preventing their crippling results. This requires a knowledge of clinical medicine in elderly persons, and the availability of specialist consultant advice for the family doctor. Some alteration, therefore, is necessary in the training of doctors and nurses, because at present they learn little, as students, of the diseases which will form a large part of their future practice.

Speaking generally, the teaching hospitals have no room to set up a new department of medicine in their buildings, but the municipal hospitals have the wards to spare, and the patients. The latter hospitals will soon become the property of the Regional Hospital Boards, and careful thought will be required to decide the best methods of co-operation between the teaching hospitals and the Boards, so as to ensure that the problem of the chronic sick is given the attention it deserves.

CORRECTION

Section of Epidemiology and State Medicine, *Proceedings of the Royal Society of Medicine*, 41, 165, March 1948.

The final sentence of Sir John Taylor's paper on "Epidemiology of Cholera", p. 176, line 2, should read: "The possession of an inoculation certificate does not of course ensure complete freedom from risk."

[October 21, 1947]

DISCUSSION ON RENAL CIRCULATION

Dr. Joseph Trueta and Dr. A. E. Barclay [Summary]: In March 1941 cases described as "crush syndrome" were recorded. Following severe crushing, usually of the lower limbs, apparent recovery was followed by progressive impairment of renal function and death from renal failure about a week after the injury had been sustained. This clinical picture was soon established as more cases were recorded. Various theories were put forward to account for the sequence of events, none of which seemed to give a satisfactory explanation. Trueta and Barnes, working in Oxford, thought that the explanation might perhaps lie in some reflex effect on the vascular supply of the kidney, causing ischæmia. They therefore produced a condition in rabbits resembling crush injury by the application of a tourniquet to one of the hind-limbs for a period of four and a half hours. It was found after removal of the tourniquet and on injecting radiopaque material into the abdominal aorta that there was active spasm of the femoral artery which might persist for days. The circulation below this zone of spasm was greatly restricted, if not actually suppressed. Further, it was noted that a similar type of spasm frequently occurred in the femoral artery of the uninjured leg and sometimes extended up the internal iliac arteries. Was it possible that a similar type of spasm also affected the renal circulation?

Owing to war conditions, it was not possible to continue the work till September 1945 when a team was formed at the Nuffield Institute for Medical Research, Oxford, to follow up clues given by these early experiments. This team consisted of a surgeon (Dr. Trueta), a physiologist (Dr. Franklin), a radiologist (Dr. Barclay) a pathologist (Dr. Daniel), and a graduate assistant (Miss Prichard).

A technique was devised by which a radiopaque substance, thorotrast, was injected through a cannula into the jugular vein. X-ray cinematograph records, which gave accurate timing of the progress of the opaque blood, were made of the vessels of the kidney as the blood passed through them. From these records on control animals, it was shown that the renal artery was visualized in three seconds and the renal vein in six seconds from the time of injection. The field of the X-ray ciné was, however, of limited size, and it was clear that information as to other vessels was needed. X-ray ciné-recording was therefore replaced by taking single large-size films at the critical times of three and six seconds from the time of the injection. These films included virtually the whole animal. It was found that after the tourniquet had been applied definite changes occurred in certain vessels and, in particular, there was definite narrowing of the renal artery and an increase in the size of the renal vein. It was also noted that sometimes the renal vein was already visible when, according to the control, only the renal arteries should have been seen. This suggested a disturbance in the circuit time of the blood through the kidney. To investigate this the X-ray ciné was used to check the times, and it was found that whereas in the normal animal the circuit time from the renal artery to the renal vein was three seconds, in the tourniquet animals it might be reduced to almost a half of this time. This could only be explained on the hypothesis that the blood had not traversed the whole kidney but had taken a short circuit, so arriving in the renal vein more rapidly.

The next stage was to make direct observations by means of laparotomy on animals that had been subjected to a tourniquet on the leg. In these experiments, the surface of the kidney was often found to be very pale and bloodless. The colour of the blood in the renal vessels was also clearly seen and it was noted that there

were frequently streams of bright arterial blood flowing with the dark blood in the renal vein. Moreover, on several occasions the *whole* of the blood seen in the renal vein was as red as in an artery. Even more striking was the fact that this vein, apparently filled with arterial blood, occasionally exhibited pulsation that was almost comparable to that in an artery. It seemed obvious from this series of observations that these phenomena could only be explained by the presence of anastomotic channels in the kidney through which the blood was short-circuited in response to the stimulus produced by the application of the tourniquet.

The next step was the injection of dyes or Indian ink, either direct into the renal artery or via the aorta. In the control, the coloured blood was at once seen to perfuse the surface of the kidney and to pass out through the renal vein; but in the tourniquet animals, although the coloured blood passed out by the renal vein, the surface of the kidney was unaffected, i.e. although the coloured blood had traversed the kidney it had failed to pass to the surface of the cortex. When these kidneys were cut in half the staining of the dye showed that in the tourniquet animal the blood had short-circuited within the kidney and that virtually none of it had reached the surface of the organ or the glomeruli in its cortex.

The short-circuit was evidently of such dimensions that it suggested an anastomotic communication that ought to be anatomically demonstrable, yet stereoscopic radiographs of injected kidneys failed to show any trace of such connexions. The short-circuit must therefore lie in vessels too small to be seen with the naked eye. It was then found by histological investigation and radiography that the main channels of short-circuit lay about the internal area of the cortex, filling the vasa recta of the medulla of the kidney. These vessels are multitudinous and are considerably larger than capillaries. They appear to be the main channels that provide this alternative route for the blood flow. Many of them arise from the larger glomeruli which Heggie has named juxtamedullary glomeruli. The suggestion is that this, and perhaps other alternative paths of flow, are an anatomical physiological feature of the vascular supply of the kidney. They are under direct or indirect control of the nervous system, for, after cutting the splanchnic nerve, the application of a tourniquet failed to produce any appreciable effect on the renal circulation. It seems clear, therefore, that in the "crush syndrome" the persistent nervous stimulation causes a short-circuit of blood away from the cortex of the kidney; and if the consequent ischæmia persists long enough, impairment of function and even necrosis will result.

It is suggested that in cases of vascular hypertension, the cortex of the kidney tends to be short-circuited and out of action too frequently. Nature's response is to raise the blood-pressure, thus opening up the cortex and bringing the glomeruli into function. If this is successful, the patient remains well, apart from the raised blood-pressure that is necessary to keep the cortex of the kidney in function, and the kidneys remain normal. It is only when the blood-pressure fails to open up the renal cortex that symptoms of uræmia develop and pathological changes occur in the kidney.

Dr. J. F. Heggie: When the rate of renal blood flow is measured directly in the normal anæsthetized rabbit by the method of Dunn, Kay and Sheehan (1931) it is found to lie between 2 and 4 c.c. per gramme of kidney substance per minute, commonly between 2.5 and 3 c.c. per gramme per minute.

When finely particulate carbon ("Hydrokollag") suspended in serum is injected into the renal artery in the normal anæsthetized rabbit, at the same rate as the blood flow therein, for two to three seconds and the pedicle immediately clipped the renal vascular architecture is clearly demonstrated and the pigment is found in the inter- and intralobular arteries, the afferent glomerular arterioles and glomeruli, and the essentially glomerular character of the circulation as described by Bowman (1842) is demonstrated. The efferent glomerular arterioles in the cortex are usually smaller

than the afferent vessels and are relatively short, they soon break up to join in the peritubular capillary plexuses. The efferent vessels of the glomeruli situated near the medulla, to which in 1941 I gave the name *juxtamedullary glomeruli*, provide the blood supply to the medulla; these vessels are large, larger than the corresponding afferent vessels, and long, and run a fair length before they break up to form very rich capillary arcades and networks around the tubules in the pyramid, the loops of Henle and the collecting tubules. A similar architecture obtains in the human kidney.

Microdissection of the glomerulus shows the afferent vessel to branch after the manner of an artery into subdivisions which give rise to capillaries; in like manner the venous capillaries unite and the efferent arteriole is formed. This point, which is not generally appreciated, is well illustrated in Bowman's paper (1842) and in Vimtrup's semidiagrammatic representation (1928).

The volumes of representative glomeruli in the rabbit kidney in the usual normal state of the circulation and in acute toxic glomerulitis in which there is extreme dilatation of all glomerular capillary loops, were obtained from measurements made on enlarged serial photomicrographs (at 2,000 diameters). The number of glomeruli per kidney was ascertained from partial and total counts—and found to be around 200,000. The glomerular capillary rate (velocity) was then computed to be 1.25 mm./sec.—when it was assumed that all the glomeruli were functioning (as there is good reason to believe is the case in the healthy mammal) and provided they were operating equally. The glomerular volume was calculated to be changed five times each second. These velocity and other values are not altogether unexpected having regard to the fact that the glomerular capillaries are interposed between arterioles and the pressure in them is very high.

In experimental renal cortical necrosis changes in the circulation within the kidney occur from the outset and Dr. Trueta and his colleagues (1947) have described blanching of the kidney cortex within two minutes of the injection of a large dose of staphylococcus toxin and the appearance of rapid red pulsatile streams in the renal vein from the seventh minute, maximal at fifteen minutes and continuing until the death of the animal five minutes later. In such acute experiments, if the minute volume of the renal blood flow remains the same and if the intrarenal pathway is via normal-sized *juxtamedullary glomeruli* alone, the glomerular volume of these is changed almost thirty times each second and the velocity is proportionately increased; but if the *juxtamedullary glomerular capillaries* are dilated (and they can so accommodate the entire normal glomerular capillary volume of blood) the rate of change of their augmented volume is five times per second and the velocity in the dilated capillaries is still at the normal rate of 1.25 mm./sec.

But in the slightly less acute experiment of this kind with which I am more familiar there appears to be practically no immediate phase of vascular contraction or medullary diversion, the initial lesion is one of general glomerular capillary dilatation, an inflammatory reaction in the true sense, which after initial hyperæmia shows gradual slowing so that between the second and third hour there is diapedesis of red blood cells and stasis in the cortex while the circulation in the medulla continues through the much-dilated *juxtamedullary glomeruli* and their ample efferents. In these animals the total renal blood flow is just below normal. Resolution occurs in a few animals which recover after a period of oliguria but in many the cortex becomes necrotic while the medulla, not so affected, by contrast enjoys a blood flow, via the *juxtamedullary glomeruli* which is increased fivefold and is changed at almost the normal rate of five times each second, or slightly less. It was with a knowledge of these changes, which I had demonstrated to the Pathological Society of Great Britain in 1941, that following the preliminary communication of Dr. Trueta and his colleagues (1946) I suggested in a letter to the *Lancet* (1946) that the diversion of the

circulation to the medulla, which they had demonstrated, was effected via the juxtamedullary glomeruli.

But these changes are the one extreme of a wide range; at the other are variations of the normal. Changes occur with the diminished blood flow of hypotension and shock which follow major hæmorrhagic accidents, and, in pregnancy, fatal anuria and cortical necrosis sometimes follow concealed accidental hæmorrhage.

Less severe hæmorrhagic accidents with marked oliguria and disturbance of filtration and tubular function (as after abortion) may be followed by recovery (Humphrey *et al.*, 1947) and important disturbances of the renal circulation occur also in the crush syndrome and other conditions, but it is not proposed to discuss at present the consequent variations of filtration and reabsorption rates, water metabolism, and electrolyte and urea retention.

 VIMTRUP, B. (1928) *Amer. J. Anat.*, 41, 123.

Dr. E. M. Darmady said that cortical necrosis following severe accident was not very common. There were, however, certain features found histologically in such cases which did fit in very well with the findings shown at the meeting. The bloodless glomeruli, the tubular venous rupture at the juxtglomerular area, and the congestion of the parts of the medullary zone were among these. He felt that it was not quite fair to compare the findings in the rabbit with the human at this stage, because one knew that experimentally it was easy to induce an ischæmia by traction on the kidney. They should be guarded before arguing from the rabbit to man.

Mr. R. H. Paramore said that little had been heard of the effect of the renal secretion on the renal circulation. Brodie (1914, *Proc. Roy. Soc.*, Ser. B., 87, 571) had stated that when the kidney is in diuresis, due to a saline injection, if one clamps the ureter, the kidney becomes almost bloodless. This fundamental observation throws light on the state of the kidney in eclampsia and in concealed accidental hæmorrhage. It is very important to observe that the association of anuria with accidental hæmorrhage only occurs when the blood, poured out into the uterus, is concealed: when the blood can freely escape by the vagina, anuria (symmetrical cortical necrosis) does not occur. Owing to the shape and structure of the kidney, when the pressure in the cortex rises (relaxation of arterioles), medullary parts are thrust towards and into the renal pelvis—just as when the pressure in the renal pelvis becomes raised (ureteric obstruction) the medullary parts of the kidney are thrust and compressed against the cortex.

The President (Professor H. P. Himsworth) said that he had been interested in the hepatic circulation and had found that in carbon tetrachloride poisoning and dietetic necrosis of the liver in rats rearrangements of the circulation occurred, not as primary phenomena, but as secondary effects due to swelling of the hepatic parenchyma compressing the sinusoids and so producing ischæmia. The relevance of these observations to the present discussion was that the same measures which produced dietetic hepatic necrosis produced necrosis of the renal cortex in younger rats and Dr. Hartroft, working in Professor Best's laboratory in Toronto, had shown that the ischæmia of the renal cortex, which was such an important factor in completing this type of necrosis, was, not a primary phenomenon, but secondary to a swelling of the renal parenchyma which compressed the cortical blood-vessels. Clearly such swelling would produce the rearrangement of the intrarenal circulation demonstrated by Drs. Trueta and Barclay, namely exclusion of blood from the cortex and its diversion through the juxtamedullary glomeruli to the medulla. While not denying that reflex nervous mechanisms might also cause such a rearrangement it was important to keep in mind the possibility that purely mechanical factors, such as parenchymal swelling, might also be of importance—perhaps more importance—in the pathogenesis of fully-developed cortical necroses.

Growth and Physical Performance of Children in Relation to Maturity

By RICHARD W. B. ELLIS, M.D.

At the present time the nutrition of the adolescent is the subject of official concern. Boys and girls in the teen-ages are being subjected to assessment on the basis of height, weight and physical performance, with a view to determining whether their growth and nutritional status are satisfactory. For the most part, the mean figures obtained for groups in the same year of age are being used for comparison with similar age-groups either before the present rationing or in different social environments, and for comparing growth of particular groups over a known period.

This assessment of growth and nutrition purely in relation to chronological age is open to certain avoidable errors, and it is the purpose of the present communication to stress the importance of grading on a maturity basis in addition to age when dealing with children from 9 years onward. This also relates more or less directly to the assessment of exogenous obesity in childhood, since some increase of fat deposition is commonly observed at or about puberty in both sexes. Thus a weight increment of 25 lb. in one year may be physiological in a particular boy of 15 at one stage of maturity and pathological in another of the same age in whom evidence of sexual maturation has not begun to appear. Although many studies on these lines have already been made, particularly in America (e.g. Baldwin, 1921; Crampton, 1908; Greulich *et al.*, 1942; Simmons, 1944), it is insufficiently realized that composite growth-curves constructed for children aged 9 to 18 will tend to smooth out the characteristic growth pattern associated with puberty, since the age-onset of puberty shows a wide physiological variation (Ellis, 1947).

An attempt has been made to define three stages of maturity on a purely clinical basis, which would make possible an approximate grading in school or industrial medical examinations. The criteria suggested are as follows:

TABLE I.—MATURITY GRADINGS

	Girls	Boys
Non-pubescent . .	Absence of breast development, pubic hair or menstruation	Absence of pigmented pubic hair; genital development infantile or minimal
Pubescent ..	Early breast development and/or pubic hair; absence of menstruation	Early genital development and/or pubic or axillary hair
Adolescent ..	Menstruation, breast development, and presence of body hair	Development of corpora cavernosa plus advanced enlargement of testis in relation to epididymis plus pubic (and axillary) hair

These criteria are obviously inadequate to serve as more than an approximate index of three stages of maturity but I hope to show that they are considerably better than none. In the case of girls, menstruation could usually be related much more accurately to ovulation if facilities were available for estimation of pregnandiol in the urine, but this is impracticable where large groups are under review. Similarly, it might be possible to subdivide "adolescence" into early or late on a clinical basis, depending on whether a regular menstrual cycle had been established and whether axillary hair was present.

In the case of boys, the absence of a well-defined stigma such as menstruation makes classification more difficult, and border-line cases will inevitably occur. Thus the appearance of pigmented pubic hair is preceded by non-pigmented vellus, and the assessment of the stage of genital development is to some extent arbitrary. In general, growth in length of the penis precedes adolescent development of the corpora cavernosa, whilst a pubescent stage of testicular development can usually be distinguished in which the body of the testis is enlarged in relation to the epididymis, is softer than in the prepubescent state, but is less than half the adult size. Penile development may precede testicular development or vice versa. For the grading of adolescence, well-marked development both of penis and of testicles is necessary, in association with pubic hair; the appearance of axillary hair is too variable to serve except as a confirmatory sign, since in some cases it was found to appear very late and occasionally in advance of pubic hair and before genital development was apparent; hair on the linea alba was only observed when adolescence was well advanced. The pitch of the voice is also regarded as confirmation of adolescence when the voice is obviously "broken", but the pitch cannot be estimated on a single examination with sufficient accuracy to be of much clinical value.

In a series of 208 boys aged 11 to 16 to whom these gradings were applied, it was found that gynæcomastia was present in none of the non-pubescent boys, in 12.9% of the pubescent, and in 32.1% of the adolescent. It bore no obvious relationship to

FIG. 1.—Percentage of boys non-pubescent, pubescent and adolescent in each year of age (9 to 18).

the presence or absence of axillary hair. Comedones were noted in 19.7% of the non-pubescent, 41% of the pubescent, and 76.2% of the adolescent boys (Ellis, 1946).

On the basis of 662 examinations, the percentage of boys graded as non-pubescent, pubescent, and adolescent in each year of age between 9 and 18 was as shown in fig. 1.

This illustrates the effect which the raising of the school-leaving age from 14 to 15

will have on the maturity of boys entering employment. Whilst at 14 the percentage of completely immature boys is greater than the percentage graded as adolescent, at 15 the percentage of "non-pubescent" boys is less than 10 and that of adolescents approximately 60. The distribution curve of pubescent boys shows a peak between 13 and 14 years (at which age the division into non-pubescent and pubescent is most even).

If the same data are replotted (fig. 2) to show the percentage of boys non-pubescent and the percentage non-adolescent in each year of age, the curves suggest that the duration of pubescence is longer in those maturing early or late than in those maturing at the mean age (Ellis, 1948).

FIG. 2.—Percentage of boys non-pubescent and non-adolescent in each year of age (9 to 18), to show duration of pubescence.

Height and Weight.—Using the maturity-grading described, an initial comparison was made of the mean height and mean weight of boys of the same year of age but of different degrees of maturity, with the result that within the age ranges studied, viz. 12 to 16 years, the groups of more mature boys were found in every instance to be heavier and taller than the groups of less mature boys of the same year of age. These boys were all resident in two schools (referred to as Schools A and B) and since comparisons were only made between boys in the same school, each group had been living under similar environment and on the same school diet as the group with which comparison was made for periods of from 3 to 10 years.

The differences in each instance between the mean heights and weights of boys of similar age but in different maturity groups were statistically significant (Ellis, 1946).

In order to determine at how early an age these differences were apparent, mean height and weight curves were constructed for each maturity-age group, and those for boys of the same age and school compared. It was found that whilst the curves tended to diverge with increasing maturity, the groups of earlier-maturing boys were in all instances heavier and taller than their later-maturing contemporaries to the earliest age for which measurements were available, i.e. in the case of School A, the sixth year of age. Whilst it cannot be argued from this that a small child will necessarily mature late or a large child early, it is of interest that differences in the average heights and weights of different maturity groups were manifest long before changes directly attributable to onset of puberty had occurred.

In order to determine more accurately the rate of growth associated with each phase of maturity, 154 of the boys examined in the two residential schools were

subsequently regraded (a year later in the case of School A, and nine months later in the case of School B), and their increase in height and weight estimated a year after the initial grading. They were grouped into those who had remained non-pubescent throughout, those who were non-pubescent on first and pubescent on second grading, those who remained pubescent throughout, those pubescent on first and adolescent on second grading, and those adolescent throughout. The age-ranges at the end of the experimental period were 12 to 13 and 13 to 15 in School A and 14 to 16½ in School B (Ellis, 1948).

Fig. 3 shows the results in the case of School B. There were no boys who remained non-pubescent throughout the experimental period 1946-7, but the rate of "non-puberty" growth is indicated by Group I in 1945-6. Whilst the differences between

FIG. 3.—Mean annual height and weight increments over a three-year period of boys aged 14 to 16½ in 1947. Group I non-pubescent on first and pubescent on second grading; Group II pubescent on first and second grading; Group III pubescent on first and adolescent on second grading; Group IV adolescent on first and second grading.

(FIGS. 2 and 3 are reproduced from *Arch. Dis. Childh.*, 1948, 23, pp. 20 and 25.)

the height and weight increments of Groups I and II (who were both pubescent on second examination), were not statistically significant, it is seen that the passage from pubescence to adolescence (Group III) is associated with a rapid acceleration in both height and weight gain. In Group IV, who were adolescent on first examination, the rapid weight gain seen in 1945-46 is continued throughout the experimental period, but gain in height is beginning to be retarded.

The findings in both schools showed an acceleration of both height and weight increment preceding the clinical manifestations of pubescence, and continuing through the period of pubescence; and a more rapid gain in both height and weight associated with attainment of adolescence, and continuing into early adolescence. The boys who passed from pubescence to adolescence, and those who were adolescent on both examinations, showed an increase in height which is nearly double and an increase in weight which is more than double that of the boys who remained non-pubescent over a twelve-month period.

Hip circumference.—It was noted clinically in the course of the examinations that the onset of puberty was in many cases associated with some degree of fat-deposition in the pelvic region and with muscular development, particularly of the buttocks. It was therefore decided to measure the circumference of the hips at the level of the great trochanter in order to see whether this bore any correlation to the degree of maturity. The pooled results in this instance are given for 267 boys aged 12 to 17

examined in 1947 from the four institutions, and are divided first into maturity groups and secondly into year-age groups.

TABLE II.—HIP-CIRCUMFERENCE RELATED TO MATURITY AND AGE

Maturity	Mean age		No.	Mean circumference (cm.)	Standard deviation	Standard error
	Years	Days				
1. Non-pubescent	12	172	35	70.34	3.20	0.54
	13	141	36	72.17	3.51	0.59
	14	216	9	73.22	2.35	0.78
2. Pubescent	12	232	19	75.37	2.41	0.55
	13	170	22	76.11	3.88	0.83
	14	163	32	76.82	3.92	0.70
	15	153	15	76.13	4.01	1.04
	16	151	8	75.08	3.22	1.36
3. Adolescent	13	234	4	81.38	4.26	2.13
	14	208	30	84.18	4.07	0.74
	15	172	32	85.36	3.98	0.71
	16	168	25	84.29	3.71	0.76

It will be seen that the mean measurements are related more closely to the state of maturity than to chronological age. Thus the means for the pubescent boys at each age are greater than those of the non-pubescent, and those of the adolescents again greater than those of the pubescent boys, irrespective of age. Amongst the boys graded as pubescent (the most homogeneous of the maturity groups), the means are closely similar, whether the boys are aged 12, 13, 14, 15, or 16 years. The differences between the means of the 12 and 15 year-old pubescent boys are not statistically significant.

Whilst there can be only limited value in a measurement which involves at least three variables (bone, muscular tissue, and fat), it is suggested that the circumference of the hips might usefully be included in the routine measurements of prepubertal and adolescent boys.

Physical performance.—Using the same groups as shown in Table II, a preliminary investigation of physical performance in relation to maturity and age was made on the basis of dynamometer readings obtained with grip and pull. The same instrument was used in each case, and the tests carried out as far as possible under standard conditions. The test of pull, however, was the less satisfactory of the two, as the range of readings was relatively small and the pull, being performed with flexed thumbs across the chest at nipple level, caused some discomfort when maximum force was exerted.

The results of the dynamometer tests, arranged as in Table II, were as follows:

TABLE III.—DYNAMOMETER READINGS (GRIP AND PULL) RELATED TO MATURITY AND AGE

Maturity	Age-group (years)	No.	Grip			Pull		
			Mean	Standard deviation	Standard error	Mean	Standard deviation	Standard error
Non-pubescent	12-13	35	69.29	11.93	2.02	22.20	5.64	0.95
	13-14	36	75.17	10.87	1.81	23.72	5.04	0.84
	14-15	9	71.33	11.66	3.89	23.33	3.40	1.17
Pubescent	12-13	19	85.63	12.53	2.87	25.00	3.88	0.89
	13-14	22	74.18	9.57	2.04	24.86	4.76	1.01
	14-15	32	83.47	12.22	2.16	25.91	4.89	0.86
	15-16	15	84.87	11.28	2.91	29.27	6.48	1.67
	16-17	8	79.50	4.21	1.49	24.75	4.63	1.63
Adolescent	13-14	4	87.50	16.01	8.00	30.50	5.32	2.66
	14-15	30	109.47	17.23	3.15	31.07	5.60	1.02
	15-16	32	116.59	19.72	3.49	31.94	5.04	0.89
	16-17	25	125.79	21.10	4.31	34.88	4.67	0.95

With the single exception of the 13-year-old pubescent boys, whose mean grip is less than that of the non-pubescent group of the same age, it is seen that these performance tests increase with maturity rather than age. Thus, with the one exception noted, all the pubescent groups give on the average higher readings than all the non-pubescent, and the adolescent groups higher than all the pubescent groups. The performance of the adolescents increases with increasing age; this is consistent with the general findings, since it is to be expected that the older adolescents will on the average be more mature than the younger ones.

Conclusion.—In assessing growth and nutrition of children between 9 and 18, maturity is almost as important as is chronological age. No composite growth curves can form a satisfactory standard of comparison for the individual case unless the curves are constructed from measurements made on children maturing at approximately the same age. The differences in mean rate of growth (as indicated by increment in height and weight over a twelve-month period) have been shown to be in the order of 100% in boys within limited age-ranges and on the same school diet but at different stages of maturity. It is suggested that if a simple form of clinical maturity grading were introduced into routine medical examination of children and adolescents in this country, it would be possible to collect data and construct standards on the basis of height, weight, age and maturity which would be of much greater value than those commonly employed. There are obvious objections to using standards prepared in a different country with different dietetic habits, climate, and social standards. It would also make it possible to determine whether the age-onset of puberty is significantly affected by nutrition, latitude, and social environment as well as by the genetic factors which can be assumed to operate. More information is required with regard to the physiological deposition of fat at puberty, and the distinction between this and pathological obesity. It is unlikely that any mathematical formula relating to height, weight, and physical performance will provide a completely satisfactory answer as to what is within physiological limits and what is not, although many such formulæ have been constructed. But these measurements, if related to both age and maturity, will have a certain value in assessing the nutrition and growth of large groups of children. It is suggested that circumference of the hips might provisionally be added to the measurements made on routine examination of children and adolescents, since this appears to bear a much closer relationship to maturity than it does to chronological age.

JOINT DISCUSSION No. 1

Section of Endocrinology and Section of Pædiatrics

Chairman—L. R. BROSTER, O.B.E., M.Ch.
(President of the Section of Endocrinology)

[March 24, 1948]

Two Brothers with Infantilism, Showing Some Features of Progeria, associated with Microcephaly, Retinal Degeneration and Intracranial Calcification.—CATHERINE A. NEILL, M.D., and M. M. DINGWALL (for HELEN M. M. MACKAY, F.R.C.P.).

I.—A. P., aged 15. Birth-weight $7\frac{1}{2}$ lb. Seemed normal until about 1 year. Walked at about $2\frac{1}{2}$ years. Cut first tooth at ? over 1 year.

II.—J. P., aged 9 years 11 months. Birth-weight 8 lb. Walked at $2\frac{1}{2}$ years. Tremor since 4 years. First tooth at over 1 year.

Both are attending a school for mentally defective children.

Family history.—Parents normal. Mother's stepbrother reported to be mentally defective but can earn a living. No consanguinity of parents; no history of dwarfism. The patients are two of four siblings: (1) A. P. (2) Male (born 17.4.34) normal. (3) J. P. (4) Female (born 12.7.40) normal.

On examination.—A. P. Very small stature, extremities relatively large. Lumbar lordosis, slightly protuberant abdomen, pes valgus, slight fixed flexion knees, gait "tottering". Pigmented moles numerous on head, neck, arms and legs. Microcephalic but no sloping of forehead; ears prominent, eyeballs sunken. Skin of face stretched, some wrinkling, elsewhere normal, rather rough on hands and feet. Hair dry and thin. C.V.S. normal (apart from retinal vascular changes). B.P. 115/60. R.S. normal. Teeth irregular, grossly carious. Gums hypertrophied. Liver enlarged $1\frac{1}{2}$ fingerbreadths. Spleen enlarged 2 fingerbreadths. Bilateral undescended testes. No secondary sex characteristics. C.N.S.: Pupils slightly irregular, very small, react very slightly to light and accommodation, very low response to mydriatics. Jerks brisk. Plantars flexor. Fundi "degenerative retinitis of the pepper-and-salt type. Optic atrophy both eyes". (Mr. Minton.)

J. P. Very similar. Spleen only just palpable. Liver enlarged 1 fingerbreadth. Blood-pressure 112/60. Teeth less carious; optic atrophy less marked but retinae similar.

Measurements	A. P.	J. P.	Normal brother, 13 years
Weight	30 lb. 5 oz.	34 lb. 14 oz.	
Height	40½ in.	44 in.	57 in.
Upper (crown-symphysis)	18 in.	19½ in.	
Lower (symphysis-sole) ..	21½ in. (R. & L.)	22½ in. (R. & L.)	28½ in.
Ratio (upper : lower) ..	0.85	0.87	
Head circumference ..	18 in.	19½ in.	
Span	38½ in.	42½ in.	59 in.

Investigations:

	A. P.	J. P.
Hb	92%	96%
R.B.C.	4.75 million	5.0 million
W.B.C.	8,400	12,000

W.R., Kahn and jelly (tuberculin) tests all negative.

	A. P.	J. P.
Serum potassium ..	22.2 mg. %	21.4 mg. %
Serum phosphate ..	3.37 mg. %	3.71 mg. %
Serum phosphatase ..	17.4 units	15.3 units
Serum calcium ..	10.0 mg. %	9.9 mg. %
Serum cholesterol ..	195 mg. %	240 mg. %
Serum protein ..	6.92 (A. 4.99, G. 1.93)	6.10 (A. 4.86, G. 1.24)
Serum chlorides ..	600 mg. %	588 mg. %
Serum sodium ..	344 mg. %	344 mg. %
Blood urea ..	38 mg. %	44 mg. %
Urea clearance ..	83% of normal	78% of normal
Thymol turbidity ..	4 units	4 units
Non-protein nitrogen	41 mg. %	50 mg. %
Urine:	Normal	Normal
Urinary amino-acid nitrogen	44 mg./100 c.c. (both within normal limits)	94 mg./100 c.c.
Urinary 17-ketosteroids (by Dr. Patterson)	2.0 mg./24 hr. (both low values)	1.1 mg./24 hr.
Sugar tolerance (1½ grammes/kilo):	Urine	Urine
Fasting	70 mg. %	84 mg. %
½ hour	200 mg. %	204 mg. %
1 hour	195 mg. %	191 mg. %
1½ hours	79 mg. %	66 mg. %
2 hours	43 mg. %	52 mg. %
B.M.R. (Dr. E. C. Pillman-Williams) — 17.5% (calc. on weight or on age)	Sugar plus	Sugar plus
		— 47.5% (unsatisfactory test)

X-rays: Skull shows intracranial calcification, probably choroid plexus. Long bones show slight generalized osteoporosis.

Mental state (Miss M. M. Dingwall).—Tests used: Merrill Palmer, Revised Stanford Binet Form L, Gesell's norms. A. P.: Chron. age 14 years 10 months. Mental age 2 years 4 months. J. P.: Chron. age 9 years 9 months. Mental age 2 years 5 months.

Although both these children are idiot one establishes a very good contact with them, and their reactions are much quicker than one would expect from this level of intelligence.

The lively emotions and the fact that the hand movements are almost adult are among the more interesting psychological observations.

[It is hoped to publish a fuller account of these two patients in the *Arch. Dis. Childh.*]

Dr. Leo Rau agreed that these two brothers were examples of a very rare condition. He had never seen anything similar in children. The main signs were the low B.M.R.; the splenomegaly; the marked hypoglycaemia; the retinal abiotrophy; and the mental changes. A similar case was shown by him at the Clinical Section on March 14, 1947 (*Proc. R. Soc. Med.*, 40, 468). This patient had in addition to the changes mentioned inner-ear deafness, and an abnormally slow water clearance. The treatment in this case was thyroid by mouth, which led to a complete disappearance of symptoms and signs.

Three Cases of Precocious Puberty.—N. F. ELLIOTT BURROWS, B.M. (for W. G. WYLLIE, M.D.).

I.—S. T., aged 7½ years.

History.—Normal baby till 1 month of age when mother noticed a white discharge from her vagina. This continued periodically. At 2 months of age she had pubic hair and her breasts were developed but she did not have any teeth until 11 months of age.

Although at 6 months a pinkish-red stain was noticed on her napkins on two occasions she did not start menstruating properly until 1 year and 7 months since when her periods have been fairly regular.

Family history.—Normal. One other sib. alive and well.

Investigations.—17-ketosteroids 2.8 mg. per day. X-ray of skull normal. Wrist X-ray showed bone age of about 12 years.

On laparotomy an enlarged uterus similar to that of a girl of 16 was found. Her left ovary contained a corpus luteum and a maturing follicle. Ventriculography showed normal filling of the ventricles. She is now 7½ years of age and becoming increasingly difficult to manage.

II.—Y. G., aged 6 years.

History.—Breasts started to enlarge soon after birth and her external genitalia developed rapidly with her age but her first menstrual period was at 4 years of age.

Family history.—Normal.

Investigations.—17-ketosteroids varied between 2.2 and 2.4 mg. per day. Ventriculography showed normal ventricular system. X-ray of skull normal. X-ray of wrists showed bone age of about 13 years. W.R. positive.

In November 1945 laparotomy was performed and a uterus corresponding to that of a girl of 16 and large cystic ovaries were found; $\frac{2}{3}$ of each ovary was removed. The left suprarenal gland seemed larger than normal. She is now very well developed with adult breasts and some axillary and pubic hair, and is menstruating regularly. Her W.R. remains positive in spite of large doses of penicillin and arsenic.

III.—D. A., aged 2 $\frac{1}{2}$ years.

History.—At the age of 3 months her "mother" noticed a white discharge from her vagina. At 6 months hair was noticed in her pubic region. At 8 months she seemed to be getting over-weight and it was noticed that her breasts were enlarging.

Family history.—Adopted child; nothing known of parents.

Investigations.—17-ketosteroids 0.5 mg. per day. Laparotomy revealed a large uterus similar to that of a girl of 16 years and also enlarged ovaries—the left being firm and the right obviously cystic. X-ray skull normal, X-ray wrists corresponds to bone age of 12 years.

The child has continued to develop and since the age of a year and a half has had regular menstrual periods.

Dr. David Nabarro said that when the child Y. G. was found at the Great Ormond Street Hospital to have a positive Wassermann reaction, he was asked to see her and to give his opinion as to the advisability of giving the child anti-syphilitic treatment.

Although he had not himself previously seen precocious puberty associated with congenital syphilis, he had since been informed by Dr. S. L. Simpson that a positive serum reaction might be related to the condition, but that the majority of such cases did not have a positive W.R.

Dr. Nabarro thought it justifiable and worth while to try the effect of anti-specific treatment in this case and with this end in view the child was transferred to the Leatherhead Emergency Hospital in April 1946. She received 1.64 mega-units of penicillin in six days and a course of sulpharsphenamine was begun during the time the penicillin was being given. She was not benefited clinically, but the Wassermann and Kahn tests and the Price's Precipitation Reaction (P.P.R.) all improved after the first course of treatment. Owing to difficulties inherent in nursing and treating the patient, details of the subsequent treatment appeared not to be available.

Despite the fact that the serum reactions were positive on several occasions, from which it might reasonably be inferred that the child had syphilis, there was practically no confirmation of this. The mother had on several occasions given a negative blood test, the child is illegitimate, the father—with unknown W.R.—has returned to his own country and there are no sibs. The patient had never shown any sign or symptom of syphilis, congenital or acquired, except the positive blood reaction and the endocrine disturbance which conceivably might have a syphilitic aetiology. The six-year-old molars and central incisor teeth looked quite normal, though this was no evidence against congenital syphilis. Dr. Nabarro would suggest resuming treatment with arsenobenzenes and bismuth until blood reactions became permanently negative, though any further improvement in the patient's condition, should such occur, might be attributable to the continued effect of the operation on the ovaries and/or to the anti-syphilitic treatment suggested.

POSTSCRIPT (5.6.48).—Report on repeat blood test (Dr. Orpwood Price): "Routine Wassermann reaction positive. P.P.R. 5 units. Routine Kahn reaction negative. Compared with the results obtained two years ago she seems to be improving. Could you let me know if this is substantiated clinically?"

I am told by the Rampton doctor that she has improved very considerably, but as she has had about $\frac{2}{3}$ of her ovarian tissue removed, in addition to her anti-syphilitic treatment, it is difficult—if not impossible—to assess the value of either line of treatment separately. (D. N.)

Dr. Raymond Greene remarked that he was pleased to see again after an interval of some years, the patient, S. T. He had investigated this case, at the request of Dr. Bruce Williamson, when she was a patient at the Prince of Wales Hospital at Tottenham and he had come to the conclusion that her disorder was constitutional.

He drew attention to Novak's work on the subject of precocious puberty (*Amer. J. Obstet. Gynec.*, 47, 20, 1944). Novak had recorded 9 patients in whom menstruation had begun between the ages of 15 months and 7 $\frac{1}{2}$ years in whom no evidence of abnormal endocrine gland or of a cerebral tumour had been found. He pointed out that in constitutional cases, as opposed to those occurring as a result of granulosa-cell tumours, normal ovulation occurred.

Precocious puberty due to other causes than constitutional abnormality was excessively rare.

The Chairman (Mr. L. R. Broster) said that both sex precocity and diabetes insipidus were clinical entities following encephalitis lethargica which affect the region of the hypothalamus. Sex precocity of adrenal origin can be differentiated from that of hypothalamic origin by means of the 17-ketosteroid test. It is raised in the former and normal in the latter.

Obesity, Hypogonadism, Hypothyroidism, Adenoma of Thyroid Gland and Failure of Growth in a Girl aged 13 years.—RAYMOND GREENE, D.M.

Always rather plump but not considered abnormal in this respect until last summer when her mother noticed a lump in her neck. Weight has rapidly increased since then. She has not grown since age of 10, and shows no sign of onset of puberty. Intelligence normal.

Her father is tall and broad; mother of normal height, somewhat plump. One brother, aged 19, normal. No family history of thyroid disease.

She has had whooping cough and measles. There have been no accidents or operations.

On examination.—Very obese. Height 4 ft. 2½ in. Weight 6 st. 1 lb. Measurements: From vertex to symphysis pubis 2 ft. ½ in.; from symphysis to ground 2 ft. 2 in.; span 3 ft. 10 in. Skin very dry; in parts showed hyperkeratosis follicularis. Hands and feet small and fingers tapering. Breast enlargement due to fat, no signs of gland tissue. No body hair, pubic hair or axillary hair. Diffuse enlargement of the thyroid gland with nodule about the size of a walnut in right lobe. B.P. 100/60. Pulse-rate, during observation in hospital, varied between 64 and 84. Temperature 97° to 98.4°.

Investigations.—X-ray skull normal. B.M.R. —35%; after five injections of 1 c.c. of thyrotrophic hormone, —3.5%. Hb 72%. Serum cholesterol 364 mg. per 100 c.c. Glucose tolerance test: Fasting blood sugar 115 mg. per 100 c.c. After 50 grammes dextrose, 166 mg., 185 mg., 220 mg., 196 mg. per 100 c.c. at half-hour intervals. No reduction of urine throughout.

Diabetes Insipidus.—J. P. M. TIZARD, M.R.C.P. (for Dr. W. G. WYLLIE, M.D.).

M. S., aged 10 years 10 months.

First seen at the Hospital for Sick Children five years ago.

History.—At 5 years 10 months of age he had suddenly begun to suffer from excessive thirst and to pass large volumes of urine. He had to get up at night for drinks of water and frequently wetted his bed, having previously had normal control of micturition. His appetite was poor.

On examination.—Thin, weight 41½ lb. No abnormal physical signs in the nervous system or elsewhere. Fundi oculi normal. Urine: No sugar or albumin. Sp. gr. 1.012. Nothing abnormal on microscopy. Mantoux 1:1000 negative. Blood W.R. negative. X-ray of skull N.A.D. C.S.F. normal. Sodium chloride excretion test was suggestive of diabetes insipidus.

In hospital without treatment the fluid intake varied between 4 and 11½ pints per day and there was always nocturnal enuresis. On pitressin 4 minims daily the symptoms were not controlled and there were occasional reactions (pallor, abdominal pain). On pitressin tannate in oil 4 minims daily the fluid intake varied between 2½ and 10 pints and there was only occasional enuresis.

After discharge in June 1943 he continued the latter dosage, but by September injections every other day sufficed to control the polydipsia, polyuria and enuresis completely. One year later injections every third day were sufficient, but the following year the effect only lasted about forty-eight hours.

In December 1946 the treatment seemed less effective (? due to relatively ineffective drug) and he had to have injections twice a day. He was admitted to hospital. On admission he appeared healthy. No abnormal physical signs. B.P. 110/90.

On daily injections of ½ c.c. of pitressin tannate in oil the intake and output were reduced to about 50 oz. a day, but he developed attacks of abdominal pain and vomiting and a superficial glossitis. There were no ill-effects from the same dosage every other day and the urinary output was consistently below 5 pints a day. Since then his daily requirements have again changed and he is now having ½ c.c. of pitressin tannate in oil (2.5 pressor units) daily. His mother now says that polyuria precedes thirst by about half an hour. Micturition six to eight times a day. Now: Weight 67 lb. (expected weight 72 lb.); Height 52 in. (expected height 54½ in.).

Comment.—This child was shown to the Section of Pædiatrics by Dr. Wyllie in May 1943 (*Proc. R. Soc. Med.*, 36, 583. Case D). Apart from slight subcutaneous thickening in the thighs there has been no local reaction to the injections of pitressin tannate in peanut oil. In the past five years he has never had injections less frequently than once in three days.

It is interesting that the onset is sudden in such a high proportion of cases of diabetes insipidus, not only in those cases with sudden causative factors such as basal fractures and operations in the region of the pituitary fossa, but also in the idiopathic form. On the other hand slowly growing gliomata or craniopharyngiomata rarely produce diabetes insipidus even if they involve practically the whole of the hypothalamus (without incidentally the anterior pituitary being affected).

Surgical Lectures of 150 Years Ago

By V. ZACHARY COPE, M.S.

SET courses of lectures purporting to cover the whole subject of Surgery have gone out of fashion. The subject is so vast and there are so many good textbooks that there is neither the possibility nor the need to give every detail in lectures. To some of us it is rather a matter of regret that any kind of set course of lectures in surgery is at the moment unpopular, for the spoken word has still many advantages over the written. One hundred and fifty years ago all or most of the facts of surgery could well be related in a course of lectures and in the absence of good textbooks it was necessary for each surgeon to give formal instruction to his pupils. Courses of lectures were usually given in the evenings. They were advertised and fees were paid by the students to the lecturer. Only a good lecturer was likely to obtain a good audience. Incompetence was never endowed. It is likely that some surgeons made considerable incomes from their lectures but at least one great surgeon did not lecture primarily to get money, for John Hunter made it quite clear that it did not pay him to lecture; he stated that he could easily earn more by pursuing his surgical practice; his reason for lecturing was at least partly to educate himself for, he said,

what more than all induced me to lecture was the great advantage every one finds by putting his thoughts in writing. A man can never tell how much he knows till he arranges his knowledge, and then he can tell how defective he is.

I have looked through the lectures of Cline, Pott, John Hunter, Abernethy and Astley Cooper of which there are many copies in manuscript in various libraries.

I found nothing to comment on or quote in the discourses of Henry Cline (1750–1827) who, though a pupil of John Hunter, did not teach more than the orthodox surgery of his time. Though he was reputed a successful lecturer his writings are devoid of originality, and are dull to read. Pott was a much more interesting teacher. Though for the most part he follows orthodox lines he does from time to time put in some philosophic remarks. Thus he stresses the importance of the knowledge of physic to a surgeon, derides the man who requires a multiplicity of instruments rather than a few simple ones, and criticizes commercialism in the profession. His remarks on the reading and writing of surgical books bear quoting.

Some by merely the perusal of books retained only theory. Those by far became the ablest surgeons in the closet and were apt in conversation, but in the practical part they were at a loss and frequently deficient. On the other hand those instituted or instructed by practice only,

without the use of reasoning or books to help them laboured under an equal disadvantage. They were able to perform an operation dextrously without knowing perhaps when it should be done or when it was necessary.

He gives advice to the student in his reading:

Writers of surgery may be divided into two classes, viz. those of general systems and those of particular diseases. The former have not time to fill up minute particular diseases. They do little more than give you the outlines and copy from one to another. The latter you should read more attentively and pay always more respect to writers of individual diseases, and at the same time pay a respect to yourself. Let your own judgement be accompanied with his system—comparing it with what your observation and practice show you and then act accordingly.

Pott was an excellent lecturer who laid stress more upon the practical part of his profession. His style was lucid and his outlook almost modern in tone. One would hardly think that the following passage was written one hundred and fifty years ago, yet it comes from Pott's lectures.

Surgery has within these fifty years been improved very much, but let not this excite your vanity but tend rather to excite your ambition by assiduity and study to further improvements, for no doubt some years hence our successors will be as much astonished at our ignorance as we at our predecessors.

John Hunter, Astley Cooper and Abernethy are in a class by themselves, a class in which Hunter was the master and the other two the pupils. Hunter was himself taught by Pott but everyone will agree with Sir James Paget's view that

though in practical surgery Pott generally appears more thoroughly instructed—with the science and the exposition of principles Hunter alone deals worthily.

The contrast between Hunter's lectures and those of others in his time is very extraordinary. It can best be illustrated by the remarks of Cline in his *Hunterian* lecture of 1824. He states:

I had the happiness of hearing the first course of lectures which John Hunter delivered. I had been at that time for some years in the profession, and was tolerably well acquainted with the opinions held by the surgeons most distinguished for their talents, then residing in the metropolis: but having heard Mr. Hunter's lectures on the subject of disease I found them so far superior to everything I had conceived or heard before, that there seemed no comparison between the great mind of the man who delivered them, and all the individuals, whether ancient or modern, who had gone before him.

Hunter's lectures are models of philosophic thought. He was certainly the only lecturer of the time who tried to make his pupils think and for that reason it is quite likely that his lectures may not have attracted so large an audience. His style of writing is not always so clear as that of Pott but he puts forward original views. To give one instance:—Hunter explains the phenomenon of referred pain clearly by diagram and satisfactorily though not quite so clearly in words.

A diseased part may sympathize with a diseased part, or a sound part with a diseased part... the impression on the mind, which does not accord with the sensation, as the liver and shoulder, has always been referred to sympathy; but I believe it is not properly sympathy, but a delusion of the mind, and perhaps may be produced in some such manner as this (shown in diagram).

Hunter's description of immunity is interesting:

The body, once affected by some stimuli, never forgets, as it were their action, and thereby is never again affected by that poison, as in the small-pox, measles etc.

Hunter had the gift of apt illustration from his own clinical experiences, as for example:

Many small wounds perhaps would do much better without any dressing than with... Almost all cutaneous sores do better without dressing, such as pimples. A young gentleman had a small pimple on his leg, to which a little ointment was applied and in a day or two the surrounding parts were covered with similar pimples; these being treated with similar applications spread until the whole leg was covered with them. When I was consulted and asked what was to be done. "Nothing." "How is that?" "Can anything be easier" I said, "Do nothing to the leg." "Then the stocking will stick to it." "Let no stocking be worn: put the boy on a pair of trousers." The advice was taken and the leg dried and healed up directly.

The interest of the lecture was often enhanced by references to contemporary surgeons—a method which is, for various reasons, seldom made use of to-day. In speaking of his operation for aneurysm Hunter commented:

Mr. Bromfield objects to every operation in this disease, and that, in the first place, from the immediate want of success in the operation, and from its being a disease of the whole arterial system: he says "I once saw this operation performed by a gentleman" (that's me, gentlemen) "upon the popliteal artery; but the difficulty of the operation, and the embarrassment which the operator underwent" [me again] "will, I dare say, deter him from performing it again"; but I am not so soon deterred, gentlemen . . . With respect to Mr. Pott's observations—but we must leave Mr. Pott to another evening, for he is tougher than the other a great deal.

What an excellent insight this comment gives us into the professional life of the time.

Humour was an ingredient of Hunter's lectures. I will give an example in which practical wisdom is mingled with disdain of current therapeutics. Hunter was lecturing on carbuncle and referred to a patient aged 70 years who had carbuncles on his back:

As neither bark nor calomel with opium had been of any service I said to David Pitcairn, Now do not let us permit this patient to be lost, while we are only using such means as experience has shown to be of little or no effect; for, David, this is a case more belonging to my province than to yours; and I being an older man than you, have seen more of them than you have, and can tell you, what perhaps you did not know, that we have no powers in this case that are known. Now David is a truly sensible man, and not governed by form; he therefore agreed but wanted to know where we were to begin. Why, with the first letter of the alphabet, and go through the catalogue of the *materia medica* so as we do not stop too long on the letter B, bark, as is the case in general.

In the event they tried *cicuta*, *sarsaparilla*, elm bark and caustic fossil alkali and the man recovered while he was taking the last two. Hunter related in his lecture how he had himself taken the alkali and since taking it had remained fairly free from boils to which he had previously been subject every spring.

Probably nothing interests a class more and certainly nothing emphasizes a point so decidedly as a personal reminiscence of the lecturer; Hunter frequently talked about himself in his lectures and I will quote one instance for it bears significantly upon his later illnesses.

Action of the vital organs may be suspended, and life continue, as was the case with myself. I had the gout in my feet three successive springs, and missed it on the fourth; when one day I was attacked with a pain so violent about the pylorus, as I thought, as no position could relieve; my countenance like that of a corpse. I took thirty drops of laudanum in tincture of rhubarb and found no relief; the pain continued, and upon examination I found no pulse, and at times found myself not breathing; I therefore forced myself to breathe. In this state I continued three-quarters of an hour: this went off gradually in about an hour, and have had no return of it since.

One could go on quoting from Hunter for a long time but I must get on to the lectures of Astley Cooper and Abernethy which really induced me to write this paper. My friend, Dr. Hobart Nixon, some years ago gave me a manuscript copy of notes of lectures taken by his great-uncle in 1824 and to this I am indebted for all the quotations from the lectures of Cooper and Abernethy. A perusal of the notes makes it clear that Cooper followed more the scientific side of Hunter's teaching while Abernethy talked little about the philosophy or science of surgery but gave very practical lectures interspersing them with numerous anecdotes and apt illustrations.

Abernethy used to treat a fracture of the femur with the patient lying on one side. He was a shrewd man and gave worldly-wise advice to his pupils. For example listen to him talking:

I remember a case that had all the symptoms of fracture as mentioned above, and the surgeon who attended the patient did not consider it as a fracture; however at last I was consulted and when I saw the patient I asked her "Did you put your foot to the ground after the accident?" "No, I could not for all the world." We then left the patient a short time to talk about the

nature of the case, and I said to the surgeon "What will the world say of you and me if we don't treat this case as a fracture and the woman should remain a cripple all her life? They will say we did not do our duty! What will they say if we do treat it as a fracture and she remains a cripple through life? That we tried every means and these were ineffectual". Then we laid the patient on her side, treated it as a fracture and she ultimately did well.

Abernethy's sound treatment of a gunshot wound by rest and simple dressings was enforced by this rather amusing case:

A gentleman living in town went to see some of his friends in the country and cockney-like went out to shoot sparrows, and cockney-like put his hand upon the muzzle of the gun, pulled the trigger and the contents went through the metacarpus; in this state a surgeon was sent for, and when he saw the case said—"it must be amputated or the patient will have tetanus, and then he'll die—but he might consult another surgeon if he wished".

A hospital surgeon was then consulted and he said—"I would not amputate for I have observed all sudden amputations after accidents prove fatal". Now if anyone could suppose that Job himself could have had two better comforters than these, he must, I am sure, have a superior imagination to mine. Well, in this difference of opinion I was next consulted as a referee and, seeing the case, I agreed that if the patient was likely to have tetanus it would be better to amputate; and then I agreed with the other surgeon—that sudden amputations after accidents were often fatal cases—but I said if I were the patient I would not have my hand removed, remarking that the parts injured were not very sensible, and that if kept quiet in splints, and supported in a tray, and inflammation of the more sensible parts kept off by the application of cold washes etc. the case would do well. The case was thus treated and the gentlemen were surprised to see how well it did—to be sure there was a little suppuration but the case did exceedingly well.

There is no doubt that Abernethy was a dramatic lecturer. He often emphasized his points by cases which, by the recorded wording, must have been related with great gusto and once heard would never be forgotten. I will give two examples, one concerning the treatment of retention of urine, and the other dealing with the reduction of a dislocated shoulder.

A young man fell from a garret window (having climbed up one night to see his sweetheart) and completely smashed his ilia and sacrum. I don't know how many fractures there were. However he was brought to the hospital, and I, being a "younger" was directed to draw off his water. I had done it three or four times when the nurse of the ward, an old woman, said to me "Lord bless you, young gentleman, you need not give yourself the trouble of coming to draw off his water, for I can make him piss when I like". I asked her how? She then thrust her fist on the lower part of his body making pressure and the urine flowed immediately.

The other case was related in these words:

I remember one summer going through the hospital square and I saw some of the pupils standing at one of the hospital doors rubbing their faces with their handkerchiefs, and were all of a perspiration, and they wished me to come and assist them. They had a dislocation of the shoulder-joint and had been trying to reduce it for more than an hour and were all tired; so I went to see the patient who was a coalman, and I never did see such a man in my life before; it was truly wonderful to behold the muscles that man had. It was certain the Pharnacian Hercules was not exaggerated; there were absolute hillocks of flesh. I said to the man "Will you allow me to try for seven minutes only? I shall not hurt you, and if I do not succeed in seven minutes I will not tease you any longer?" "Oh, yes sir." So I put a towel round the man's arm and made gradual extension. "Does this hurt you?" "Oh, no." "Well, I shall not hurt you, it will soon be right." I had not acted in this way long before the man called out "Lord bless you sir, that will never do, I, I'll put it off till tomorrow." "Nay" I said, "but you gave me seven minutes to try and I shall not try longer." At last he became more and more impatient and said "Lord bless you sir, I, I, shall fa- faint!" and it was in.

Nowhere have I ever read such an unforgettable account of the effect of steady prolonged traction in overcoming powerful muscular resistance. These extracts sufficiently show the qualities of Abernethy as a lecturer—not scientific nor philosophical but practical and dramatic.

Astley Cooper was probably the most able of the lecturers in the period we have chosen. He gave lectures which are even now interesting to read; they were based upon a sound anatomical knowledge and were often illustrated by the account of experiments on animals or by the recounting of clinical cases. He combined the

scientific with the popular. He had sat at the feet of John Hunter and he seems to have been imbued with something of his master's spirit. His lectures were probably more popular than Hunter's for he spent less time in theoretical disquisitions. Here are some extracts to show how interesting he could make his lectures. First there is his view on the question of the cause of inflammation:

It is generally said that air admitted into an abscess or into a wound will be productive of inflammation. Now air has no power to produce inflammation in the body. Dr. Haighton with a view to prove all this or to explain it took a living dog and made an opening in the tunica vaginalis testis (which has a direct communication with the cavity of the abdomen, but this is not the case in the human subject)—well, he made an opening in the tunica vaginalis and blew in air, till the abdomen became swelled and quite tense; in the course of a few days the swelling went down, and the dog quite recovered—however no inflammation followed. I think this an ingenious experiment of Dr. Haighton's. Air does not produce inflammation in wounds.

A young man who did not like the idea of going as a soldier endeavoured to make himself as it were a patient or sick person with a view to get off by going before a surgeon to examine him and say he was not capable of performing his military office; Well, what did he do? He made a very small opening in his scrotum, and then with a long pipe blew air in at the aperture which made a very large tumour indeed and appeared as if he had got an inguinal hernia—he walked nine miles to the surgeon and nine miles back again, but of course the surgeon was too well aware of the case as to be deceived. Still no inflammation followed this case. Inflammation can arise without the admission of air. It is the division of the vessels in the part that produces inflammation.

The story is a good one but the disproving of one theory merely led to the propounding of another quite as unlikely.

Cooper's colloquial style is well illustrated in the following:

The definition of adhesive inflammation consists in the effusion of fibrin whereby the parts surrounding become glued together. By this adhesive process cures are much sooner effected—in fact what cure would be effected without it? What was the state of surgery before Mr. Hunter found out this and published it? How widely different to what it is at this present time!

Formerly if a large portion of the scalp should be torn off from one part of the cranium by accident, O! The surgeon directly cut it completely off, for it was impossible so large a piece of scalp should again unite with the bone. Well, such was the practice once amongst the surgeons; and were they to arise from their graves and come amongst us now they would stand amazed. What if you were to be asked at the College "What would you do, sir, in a case where the scalp was torn off from part of the cranium? Would you say 'I would cut it off'?" Depend upon it, if you did you would be cut off too.

Most of us have read of the extreme anxiety displayed by Astley Cooper on the occasion of his removing a sebaceous cyst from the scalp of King George the Third; one may be able to understand his anxiety after hearing this story related in his lectures:

Wounds of the scalp are not so trifling as they at first might appear. Inflammation very often follows, erysipelas etc. and many die in consequence of the injury done to the scalp. . . . I will mention a case. I was called upon to remove a tumour from the scalp of a lady; it was unfortunately attached to the tendon of the occipito-frontalis muscle and I necessarily had to remove a part of this tendon. The operation was done on a Wednesday, she seemed quite well after its removal, but on the Sunday she was seized with rigor, succeeded by heat—she became feverish and on the Tuesday she died. Therefore you will I trust be upon your guard and never make an unnecessary cut on any part of the scalp for the practice is dangerous and you will not know what may follow such a wound.

We are all aware that Lord Lister introduced catgut into surgery but perhaps we do not all know that Astley Cooper tried the same substance for ligatures. Here is the account:

Different kinds of ligatures have been proposed such as those composed of animal matter, thinking they might become absorbed. In one or more cases I applied catgut round the arteries of a dog—and another of silk. I then closed the wound and allowed it to heal, but I cut off the ligature close to the artery. After a few days I cut down to the artery and I found that the silk ligature was detached or separated from the artery and was making its way to the surface; on the other hand the catgut ligature had separated itself and had buried itself in a kind of cyst. I know not how long this latter ligature might remain there before it became absorbed,

but perhaps it never would be absorbed. As for cutting the ligature off close to the artery you must not adopt this plan for in all probability ulceration will follow and also a tardy cure.

Cooper in his lectures was constantly referring to Hunter's work and he gave a full description of Hunter's operation for popliteal aneurysm; but the most interesting description is that which he gave of his own case in which he ligated the abdominal aorta. He explained that the aorta could become obliterated by disease without gangrene of the lower limbs resulting, and he had found that at least in dogs, the aorta could be ligated without serious damage to the lower limbs. He commented "tying the aorta is an operation that no man, I think, would covet". Concerning his own case he went on:

I do not know whether I should say anything about this, for you know there was a great deal said against me after I had tied this vessel—however I trust you may never have occasion to perform so terrible an operation.

Perhaps you may enquire "Would you do it again?" I answer "yes, tomorrow, if I had the opportunity", for I shall never be swayed or ruled by other people, by those who know nothing about the matter; I should listen to them as much as I should to the buzzing of a gnat or the hissing of a goose. The man on whom I tied the abdominal aorta had an inguinal aneurysm burst, and a violent gush of blood came forth, quite terrible to behold; well, was I to stand and see the man die from hæmorrhage when at the same time I thought I had it in my power to preserve his life? Certainly not, therefore I thought it my duty to tie the abdominal aorta, the only means left to save his life. I made a large semilunar incision in front of the abdomen taking care not to cut the umbilicus as this might occasion great pain. I made an opening into the front of the abdomen about four or five inches in length; then laying aside my knife I passed my finger down to the left side of the spine where I felt the vessel beating most famously, in fact at first it was appalling to me. I then carefully separated the artery from all the parts surrounding and succeeded in passing the needle round it; when the ligature was tied hæmorrhage ceased.

On the next day as I was entering the ward where the man lay, I was highly pleased, for I observed the man placing himself in a certain position as if preparing himself ready (for) when I came: I asked him how he felt himself? "Oh", he said "I feel very well sir, very well indeed. I have no particular pain." However the next day he died, but I never knew the cause of this sudden death. I really thought at one time the man would have survived the operation.

This dramatic incident is a fitting finale. In these brief extracts you will note most of the virtues which are peculiar to the spoken word. The emphasis laid on the essential point, the apt illustration to enforce the principle, the personal experience calculated to keep the student's attention, the dramatic demonstration, the witty allusion, the humorous story, even the sharp criticism of contemporaries—all these combine to make these discourses memorable. We have lost something by the abolition of such lectures.

Section of Surgery

[February 4, 1948]

DISCUSSION ON THE SURGICAL TREATMENT OF HYPERTENSION

Professor Robert Platt: Most speakers and writers on the subject of sympathectomy for hypertension conclude by saying that we cannot yet finally assess the results of this operation. That may indeed be true, but I think we know quite enough to say that sympathectomy for hypertension is a formidable and unphysiological procedure, that the results on the whole are disappointing, that the claims of surgeons must be accepted only after close and careful scrutiny; but that in some cases, which are quite unpredictable, a significant, lasting and beneficial reduction in blood-pressure is achieved.

That the procedure is formidable none I think would deny; that it is unphysiological is also self-evident. I do not like the word unphysiological but it is in common use, and is a brief and convenient way of saying that the procedure is one which does not restore normal function. Few operations do, but at least they closely approach this ideal in some instances, for example the removal of an insulin-adenoma, or a parathyroid tumour. The cause of human essential hypertension being unknown or unproved, an attack on purely physiological lines cannot yet be designed. Despite all the arguments which have been presented on the other side, I believe that the weight of evidence is in favour of a renal origin for essential hypertension. One cannot concisely summarize the reasons for this view and it must suffice to say that physiological studies in essential hypertension do not show it to differ in any significant respect from experimental hypertension due to renal ischaemia; neither can essential hypertension be distinguished by its effects from renal hypertension in the human subject. Vascular changes in the kidney can be found in over 90% of cases of essential hypertension (Talbot *et al.*, 1943) and clearance studies show a diminished renal blood flow. Although Goldring and Chasis (1944) make great point of the fact that this may be the result and not the cause of the hypertension, and that there is no evidence of ischaemia in the sense of a reduction in blood flow per unit of functioning tubular mass, this can be countered by the fact that similar findings are recorded in animals with experimental renal hypertension (Goldblatt, 1947).

For similar reasons the fact that neither renin nor hypertension has been demonstrated in excess in the systemic blood in chronic human hypertension cannot be used as an argument against the renal origin of hypertension, for these substances cannot be demonstrated in the chronic phase of experimental renal hypertension in animals, yet removal of the ischaemic kidney, or of the constricting clamp in these experiments, may cause a return of pressure to normal, which is surely proof of its renal origin.

Even if human essential hypertension is of renal origin, it is clear that its effects on the cardiovascular system are eventually serious, since most hypertensive patients die of cardiac failure or of cerebral vascular accidents. We are therefore justified in using unphysiological means to reduce the blood-pressure if they can be shown to have no serious untoward consequences. Sympathectomy seeks to reduce total peripheral resistance—and therefore to alleviate diastolic hypertension—by removing sympathetic tone from the splanchnic area and from the legs.

Mitchell (1947) has shown that in order to be reasonably certain of denervating the splanchnic area, the sympathectomy must extend as high as the fourth dorsal ganglion and as low as the second or third lumbar. This is more extensive than most of the operations performed at the present time. Denervated structures are hypersensitive to adrenalin (White and Smithwick, 1942) so that even a minimal remaining sympathetic nerve supply may, through its chemical effector mechanism, have widespread effects (Mitchell, 1947). These may be reasons why the results of sympathectomy are so unpredictable at the present time. Another reason why results are inconstant may be that sympathetic nervous tone is only one of several factors in the maintenance of peripheral vascular resistance. If one postulates that arteriolar contraction is a resultant of intrinsic vascular tone, sympathetic nervous tone and hormonal control (adrenal cortex), to which is added renal humoral control in hypertensive patients (fig. 1a and b), then sympathectomy will lower the blood-pressure by minimizing one of the factors (fig. 1c). But if, as seems probable, there is for each individual a maximal arteriolar constriction, which would seem usually to be represented by a diastolic pressure of 140 to 160 mm., and the sum of the factors already exceeds that which is necessary to produce this maximum contraction, then removal of sympathetic tone may have no effect (fig. 1d and e). This may explain the failure of sympathectomy in some cases of malignant hypertension but such an explanation is purely hypothetical and I would not wish it to be

but perhaps it never would be absorbed. As for cutting the ligature off close to the artery you must not adopt this plan for in all probability ulceration will follow and also a tardy cure.

Cooper in his lectures was constantly referring to Hunter's work and he gave a full description of Hunter's operation for popliteal aneurysm; but the most interesting description is that which he gave of his own case in which he ligated the abdominal aorta. He explained that the aorta could become obliterated by disease without gangrene of the lower limbs resulting, and he had found that at least in dogs, the aorta could be ligated without serious damage to the lower limbs. He commented "tying the aorta is an operation that no man, I think, would covet". Concerning his own case he went on:

I do not know whether I should say anything about this, for you know there was a great deal said against me after I had tied this vessel—however I trust you may never have occasion to perform so terrible an operation.

Perhaps you may enquire "Would you do it again?" I answer "yes, tomorrow, if I had the opportunity", for I shall never be swayed or ruled by other people, by those who know nothing about the matter; I should listen to them as much as I should to the buzzing of a gnat or the hissing of a goose. The man on whom I tied the abdominal aorta had an inguinal aneurysm burst, and a violent gush of blood came forth, quite terrible to behold; well, was I to stand and see the man die from hæmorrhage when at the same time I thought I had it in my power to preserve his life? Certainly not, therefore I thought it my duty to tie the abdominal aorta, the only means left to save his life. I made a large semilunar incision in front of the abdomen taking care not to cut the umbilicus as this might occasion great pain. I made an opening into the front of the abdomen about four or five inches in length; then laying aside my knife I passed my finger down to the left side of the spine where I felt the vessel beating most famously, in fact at first it was appalling to me. I then carefully separated the artery from all the parts surrounding and succeeded in passing the needle round it; when the ligature was tied hæmorrhage ceased.

On the next day as I was entering the ward where the man lay, I was highly pleased, for I observed the man placing himself in a certain position as if preparing himself ready (for) when I came: I asked him how he felt himself? "Oh", he said "I feel very well sir, very well indeed. I have no particular pain." However the next day he died, but I never knew the cause of this sudden death. I really thought at one time the man would have survived the operation.

This dramatic incident is a fitting finale. In these brief extracts you will note most of the virtues which are peculiar to the spoken word. The emphasis laid on the essential point, the apt illustration to enforce the principle, the personal experience calculated to keep the student's attention, the dramatic demonstration, the witty allusion, the humorous story, even the sharp criticism of contemporaries—all these combine to make these discourses memorable. We have lost something by the abolition of such lectures.

President—Sir MAX PAGE, K.B.E., C.B., D.S.O., M.S.

[February 4, 1948]

DISCUSSION ON THE SURGICAL TREATMENT OF HYPERTENSION

Professor Robert Platt: Most speakers and writers on the subject of sympathectomy for hypertension conclude by saying that we cannot yet finally assess the results of this operation. That may indeed be true, but I think we know quite enough to say that sympathectomy for hypertension is a formidable and unphysiological procedure, that the results on the whole are disappointing, that the claims of surgeons must be accepted only after close and careful scrutiny; but that in some cases, which are quite unpredictable, a significant, lasting and beneficial reduction in blood-pressure is achieved.

That the procedure is formidable none I think would deny; that it is unphysiological is also self-evident. I do not like the word unphysiological but it is in common use, and is a brief and convenient way of saying that the procedure is one which does not restore normal function. Few operations do, but at least they closely approach this ideal in some instances, for example the removal of an insulin-adenoma, or a parathyroid tumour. The cause of human essential hypertension being unknown or unproved, an attack on purely physiological lines cannot yet be designed. Despite all the arguments which have been presented on the other side, I believe that the weight of evidence is in favour of a renal origin for essential hypertension. One cannot concisely summarize the reasons for this view and it must suffice to say that physiological studies in essential hypertension do not show it to differ in any significant respect from experimental hypertension due to renal ischaemia; neither can essential hypertension be distinguished by its effects from renal hypertension in the human subject. Vascular changes in the kidney can be found in over 90% of cases of essential hypertension (Talbot *et al.*, 1943) and clearance studies show a diminished renal blood flow. Although Goldring and Chasis (1944) make great point of the fact that this may be the result and not the cause of the hypertension, and that there is no evidence of ischaemia in the sense of a reduction in blood flow per unit of functioning tubular mass, this can be countered by the fact that similar findings are recorded in animals with experimental renal hypertension (Goldblatt, 1947).

For similar reasons the fact that neither renin nor hypertension has been demonstrated in excess in the systemic blood in chronic human hypertension cannot be used as an argument against the renal origin of hypertension, for these substances cannot be demonstrated in the chronic phase of experimental renal hypertension in animals, yet removal of the ischaemic kidney, or of the constricting clamp in these experiments, may cause a return of pressure to normal, which is surely proof of its renal origin.

Even if human essential hypertension is of renal origin, it is clear that its effects on the cardiovascular system are eventually serious, since most hypertensive patients die of cardiac failure or of cerebral vascular accidents. We are therefore justified in using unphysiological means to reduce the blood-pressure if they can be shown to have no serious untoward consequences. Sympathectomy seeks to reduce total peripheral resistance—and therefore to alleviate diastolic hypertension—by removing sympathetic tone from the splanchnic area and from the legs.

Mitchell (1947) has shown that in order to be reasonably certain of denervating the splanchnic area, the sympathectomy must extend as high as the fourth dorsal ganglion and as low as the second or third lumbar. This is more extensive than most of the operations performed at the present time. Denervated structures are hypersensitive to adrenalin (White and Smithwick, 1942) so that even a minimal remaining sympathetic nerve supply may, through its chemical effector mechanism, have widespread effects (Mitchell, 1947). These may be reasons why the results of sympathectomy are so unpredictable at the present time. Another reason why results are inconstant may be that sympathetic nervous tone is only one of several factors in the maintenance of peripheral vascular resistance. If one postulates that arteriolar contraction is a resultant of intrinsic vascular tone, sympathetic nervous tone and hormonal control (adrenal cortex), to which is added renal humoral control in hypertensive patients (fig. 1a and b), then sympathectomy will lower the blood-pressure by minimizing one of the factors (fig. 1c). But if, as seems probable, there is for each individual a maximal arteriolar constriction, which would seem usually to be represented by a diastolic pressure of 140 to 160 mm., and the sum of the factors already exceeds that which is necessary to produce this maximum contraction, then removal of sympathetic tone may have no effect (fig. 1d and e). This may explain the failure of sympathectomy in some cases of malignant hypertension but such an explanation is purely hypothetical and I would not wish it to be

taken too seriously or my diagrams to be interpreted literally. They are not intended to illustrate quantitative relationships.

The same mechanism might account for the failure of depressor agents such as hypnotics and tetra-ethyl ammonium compounds to lower blood-pressure significantly in many of the severe cases.

Let us now examine the statements I have made on the results of sympathectomy, starting with my assertion that recorded results must be examined with close scrutiny before acceptance. Every physician knows that in many cases of hypertension there are wide, naturally

FIG. 1.

occurring, variations in blood-pressure. This seems to be especially true of the younger patients with essential hypertension, though I make that statement with reserve, as Hammarström (1947) throws some doubt upon it. Furthermore, there is considerable evidence that until the diastolic pressure has reached levels of at least 115 or 120, hypertension does not carry any increased immediate risk to life. All are agreed that women tolerate hypertension better than men, and we are all familiar with cases in which a severe, though often symptomless, hypertension has been sustained for several years without apparent progression or deterioration. Finally, in a large number of cases hypertension in its earlier stages is a symptomless condition, only becoming troublesome when an anxiety state is superimposed by the discovery of a high blood-pressure, so that we must beware of judging the result of an operation by its effect on symptoms. For all these reasons we cannot properly appraise the recorded results of sympathectomy unless we are informed of the age and sex of the patients, whether the blood-pressures quoted are maxima or minima and under what conditions they were taken both before and after operation. These data are not available in all or even in most of the published literature.

Of recent papers those by Poppen and Lemmon (1947), Palmer (1947) and Hammarström (1947) carry most conviction and my statements as to the results of sympathectomy are largely derived from them, supplemented by my own experience.

Results are bound to vary according to methods of selection, and for this reason I think that some of the statistically poorer results may represent a greater gain to the patients. For instance, if only cases of malignant hypertension were included, and if the operation was only successful in 10 to 20%, the results would be significant, whereas one is bound to be sceptical of claims of improvement even in 70% of mild cases of labile hypertension.

For these reasons I think that even as small a series as my own is instructive for each case is personally known and investigated. Our method of selection has been individual and, to a considerable extent, arbitrary. We have tried to exclude both extremes. On the one hand we have rejected elderly persons (most of those over 50) and those with poor renal function, advanced cardiac changes or serious cerebral complications. On the other hand we have refused to recommend such a serious operation to persons with only moderate elevation of diastolic pressure (for instance average levels of 110). Above all we have tried to assess what the prognosis would be without operation. If we felt that it was reasonably good we have discharged the patient after investigation, to be reassessed in say six months' time. Undoubtedly

such a selection is hard on the surgeon but it means that results obtained should be worth while.

The results we have tried to evaluate again on the grounds of prognosis. I have asked myself whether in my opinion the patient's diastolic pressure has been brought from a dangerous level to within a range of comparative safety. If so I have recorded the result as good. I have recorded as "worth while" cases in which there has been a significant fall of diastolic pressure (over 20 mm.) even though, because of high initial figures, the actual level is not as low as one would like. All the remainder I have recorded as failures. The actual figures are seen in Tables I and II and it is interesting that the average fall of diastolic pressure in the "good" results is not as great as in the "worth-while" cases, owing to the higher initial level of the latter group.

TABLE I.—RESULTS OF SYMPATHECTOMY (JANUARY 1948)

Still incomplete or too recent	10
Failed to complete operation owing to complication, &c.	4
Operative deaths	3
Failed (after complete operation)	9
Worth while result	8
Good result	4

Total 38

TABLE II

Group	Average age	Av. of max. and min. pre-op. pressure	Post-op. pressure (lying)	Change in diastolic pressure
Good (4 cases)	34	186/122	140/100	-22
Worth while (8 cases)	39	227/139	182/111	-28
Failed (9 cases)	35	210/129	225/132	+3

The series includes 8 cases of the malignant type of hypertension (with papilloedema). 2 of these failed to complete the operation owing to complications (both died later), 3 were unimproved (1 has died), the remaining 3 cases have all lost their papilloedema, with a significant fall of pressure in 2 and a considerable postural hypotension in the third, whose sympathectomy is still incomplete. The experience of seeing papilloedema resolve and blood-pressure fall in this otherwise intractable condition is a very gratifying one, even if good results are few and inconstant.

I have tried to see if pre-operative tests aid in the selection of patients. On our small series one cannot say that Smithwick's assertion is confirmed that a pulse-pressure of less than half the diastolic is a favourable sign. There is considerable evidence that a bad response to depressor tests with sodium amytal or pentothal will be followed by failure of the operation, but there are occasional exceptions. The cause of the hypertension does not seem to influence the outcome. Our favourable cases have included examples of chronic pyelonephritis and of hypertension following pre-eclamptic toxæmia.

The Smithwick operation was performed on the earlier cases in my series by Professor Geoffrey Jefferson or by Mr. H. T. Simmons. Lately Professor A. M. Boyd has been employing a more extensive operation. It is too early to say whether the results are better.

Finally a word on the permanence of the effects. My cases (all post-war) have been followed for a maximum of less than two years, but even in that time we find that those improved after six months have remained improved after eighteen months. Hammarström (1947) makes the same generalization after a follow-up period up to six and a half years in some cases, though Palmer (1947) finds that the number of successes becomes less as the years go on.

To the question as to whether sympathectomy is worth while I would therefore answer that it is, for it is the best we have to offer and can probably alter the prognosis of severe hypertension favourably in from 25 to 50% of cases. When the pressure falls, headaches and cardiac symptoms improve and retinal changes may clear up. Improvements in cardiac size and electrocardiogram are often recorded.

We might now consider what remains to be done. We still have to answer two questions of major importance, the first is whether an operation extending up to the fourth dorsal ganglion is better than the Smithwick procedure, and the second is whether the failures are due to failure of sympathectomy or failure to sympathectomize. In other words does hypertension persist in spite of denervation or because denervation has not been achieved? Professor Boyd has embarked upon an attempt to find the answers to these questions and I will not prejudge the results.

Sympathectomy for hypertension is a formidable procedure. The results are often disappointing because they are inconstant, unpredictable and difficult to assess, but in some cases a significant, lasting and beneficial reduction in blood-pressure is achieved. It is therefore worth attempting in younger patients where the prognosis without operation is judged to be unfavourable, provided that the case is not foredoomed to failure by renal insufficiency, severe cardiac or cerebral symptoms or advanced arteriosclerosis.

Mr. D. W. C. Northfield: I propose to review our experience at the London Hospital of 46 cases of severe hypertension in which sympathectomy has been performed. This is a highly selected series of cases, for operation has been carried out only on those patients in whom the medical prognosis was known to be bad. The majority are cases of malignant hypertension or of renal disease with severe hypertension. Cases of uncomplicated benign hypertension have been avoided, owing to the impossibility of assessing prognosis in such patients. There were 39 patients (20 males, 19 females) with severe primary or essential hypertension, and 7 patients (4 males, 3 females) in whom the hypertension had developed secondary to renal disease. Five of the second group of patients had chronic nephritis, in one known to be of ten years' duration; one patient had bilateral hydronephrosis; and in one a nephrectomy for unilateral pyelonephritis and hydronephrosis had failed to improve his condition. The records will be analysed for the most part in three groups—males and females with essential hypertension, and cases of "renal" hypertension. All the patients have been seen by physicians, and for the most part by both Dr. Horace Evans and Professor Clifford Wilson who have a particular interest in these diseases.

In all these patients, frequent observations of the blood-pressure were made, though the sodium amylal test was not carried out. Routine renal function tests included urea concentration, blood urea, phenolsulphonphthalein excretion, and excretion urography. The fundi were examined by several observers, with special attention to the presence or absence of papilloedema, of hæmorrhage and of exudate, and the state of the retinal vessels. In many cases an E.C.G. and a cardiological report were obtained. Some patients had been under observation for a considerable period of time before operation, and this applies in particular to those with "renal" hypertension.

Using the state of the fundi as a criterion (Table I) the majority (approximately 80%) showed evidence of malignant hypertension although in some, judging by the known pre-operative duration of the hypertension, it seems probable that a malignant phase had supervened on a benign. Thus, in all 46 cases, normal fundi were present in only 4, and in only 3 others were the changes limited to tortuosity and irregularity in calibre of the arteries. In one-half (23) of the patients there was moderate or florid papilloedema; and in 14 others this was mild or doubtful, and in this group, with mild or doubtful papilloedema, there were also hæmorrhages and exudate in rather more than half. In two cases there were hæmorrhages and exudate without papilloedema. If the patients with hypertension secondary to renal disease are excluded, papilloedema to a greater or less degree was recorded in 33 of the 39 cases and it was more commonly present in males than females in the proportion of 20 to 13, though the sexes were almost equally represented (20 males, 19 females). Papilloedema was present in 5 of the 7 cases of renal hypertension.

TABLE I.—FUNDUS ABNORMALITIES

All cases	
4	Normal
2	Hæmorrhages and exudate
3	Tortuosity and irregular calibre of vessels
14	Papilloedema—mild or equivocal
23	Papilloedema—moderate to florid
46	

The hypertension was of a severe degree in many cases, the diastolic averaging 135 mm.Hg in the males and 131 in the females in the group of E.H.T. and approximately similar in the patients with R.H.T. To arrive at these figures, the lowest record during the month preceding operation has been selected, thus giving the patient the benefit accruing from rest in bed. The extreme figures were 190/100 and 140/110, on the one side, and 300/180 on the other; there were three patients with a diastolic pressure of 180.

The main features of the disease have been analysed in order to demonstrate their incidence in the patients with essential hypertension; this has not been attempted for the cases with renal hypertension as they are too few. Fundus changes of unequivocal degree are denoted

by P; evidence of disturbance of cerebral function, i.e. epileptiform attacks, loss of consciousness without convulsion, attacks of hemiparesis, transient or permanent, and mental deterioration by Ce; symptoms or signs believed to have indicated early or late heart failure by Ca; severe headaches by H; and impairment of renal function to a greater or less degree by R, assessed on the basis of all the tests of renal function. In each case a maximum of 5 can be scored, if the patient presented with all five features, and a lower score indicates less extensive manifestations; one must not read too much into these figures owing to the small number of cases, but the method may prove valuable in the future. Amongst the 20 males (Table IIa), 3 scored 5, 6 scored 4, 6 scored 3, and 5 scored 2; in the 19 females (Table IIb) the scoring was throughout on a lower level, namely, none scored 5, 2 scored 4, 9 scored 3, 5 scored 2, and 3 scored 1. This distribution of disease manifestations will be referred to again when reviewing results.

The Adson operation was employed until the end of 1943; this comprised a subdiaphragmatic resection of the splanchnic nerves and of the upper 2 or 3 lumbar sympathetic ganglia; 10 patients underwent this operation, with 2 operative deaths. In the remaining 36 patients the Smithwick operation has been carried out with 6 deaths; in this operation the ganglionic chain has been removed from T9 to L2 inclusive (with a few exceptions, in which T10 has been the upper level) and the great splanchnic nerves from a similar or higher level, to their termination in the coeliac ganglion. Comment upon operative details will be made later.

There were two patients with essential hypertension in whom the operation was not undertaken on the second side on account of their rapid deterioration as a result of the disease, and they died eighty-one days and ninety-six days respectively after the first stage, one from cerebral haemorrhage and heart failure, and the other from heart failure. There are 29 patients with essential hypertension who survived the bilateral operation and all have been "followed up" (fig. 1). Dealing separately with the sexes, of the 12 men 5 have since died, one enjoying a very active life for four years and ten months and another for two

years and four months. The results amongst the 17 females are rather better, for there have been 6 patients who have lived for two years or more; only 2 patients have died, and they survived three years and ten months and three years and two months respectively, living fairly actively. Combining the results of operation on the 29 male and female patients with E.H.T. we find that 8 of them survived for two years or more although half of these subsequently died. All patients with renal hypertension survived the operation and only 1 has died four years and four months later.

Let us return now to an analysis of all cases of E.H.T. including those who died of the disease or of the operation, using the symbols and marking according to the manifestations of the disease, headache (H), papilloedema (P), cerebral (Ce), cardiac (Ca), and renal (R) deterioration. The maximum marks for each case is 5.

TABLE IIA

MALES—E.H.T.

Deaths : operative	5	5	4	4	4	4	=	6 cases
subsequent	4	3	3	3	2	2	=	7 cases
N.B.—Those who died after two years four months and four years ten months, scored 2 each.								
Still alive	5	4	3	3	3	2	=	7 cases
N.B.—Longest duration one year ten months and one year one month, scored 3 each.								

The analysis according to the numbers of patients in each symptom group :

	P	Ce	Ca	H	R
Deaths : operative 6 patients	6	3	6	5	6
subsequent 7 patients	7	1	5	3	3
Still alive : 7 patients	7	3	5	7	1

TABLE IIB

FEMALES—E.H.T.

Deaths : operative	4	3	=	2 cases
subsequent	3	2 (at 3 $\frac{1}{2}$ and 3 $\frac{1}{2}$)	=	2 cases
Still alive : 4-3-3-3-3-3-3-2-2-2-1-1-1			=	15 cases
N.B.—Longest duration two and a quarter years.				

Analysis according to numbers of patients in each symptom group :

	P	Ce	Ca	H	R
Deaths : operative 2 patients	2	1	0	2	2
subsequent 7 patients	2	0	1	1	1
Still alive : 15 patients	9	6	9	11	3

In those dying from the operation there are more frequently to be found manifestations of the disease in all the important systems, and indeed operation might well be refused in a patient in whom there are papilloedema, present or past evidence of cerebral and cardiac deterioration, severe headache, and impairment of renal function. As would be expected, in those patients who survived for relatively long periods the incidence of the disease is generally manifested in fewer directions. These analyses and the operative mortality show that women prove better subjects, and that the disease is less severe in them. It is probably significant that renal impairment was much less frequent amongst the survivors, i.e. only present in one of the 7 males although all of them fell in the P and H groups and 5 in Ca group; and only present in 3 of the 15 females where 9 were in P group and 11 in H, and 9 in Ca.

The results may also be examined according to the fundus changes (Table III). Amongst the 20 males with essential hypertension there were 12 patients with moderate or florid papilloedema and of these only 3 survive, all recent cases (two, three and four months). Three died following operation, and amongst those who died subsequently, one lived for four years and ten months. There were 7 others with papilloedema which was mild or equivocal and of these 3 are still alive (one for one year and one month). One case in which there was no papilloedema but retinal hæmorrhages and exudates were present is alive one year and ten months after operation. In the group of 19 females, there were 8 with moderate or florid papilloedema and of these 5 still survive, to a maximum of two and a half years, and of those who died 2 patients survived for three years and ten months and three years and two months. Of 5 patients in whom the papilloedema was mild or equivocal 4 are living, up to a maximum of two and a quarter years. In the 7 patients with renal hypertension, papilloedema was moderate or florid in 3, mild or equivocal in 2 others; all are alive, except one who died four years and four months after operation.

TABLE III.—RESULTS IN CASES WITH PAPILLOEDEMA

MALES :

Moderate or Florid	12
Still alive (two—three—four months since operation)	3
“Operative” deaths	3
Subsequent deaths (maximum survival four years ten months)	6
Mild or Equivocal	7
Still alive (to a maximum of one year one month)	3
“Operative” deaths	3
Subsequent deaths (seven months)	1

FEMALES :

Moderate or Florid	8
Still alive (to a maximum of two and a half years)	5
“Operative” death	1
Subsequent death (after three years ten months and three years two months)	2
Mild or Equivocal	5
Still alive (to a maximum of two and a quarter years)	4
“Operative” death	1

No patient was refused operation solely on account of the height of the blood-pressure. Amongst the 20 males there were 6 with a diastolic pressure of over 150 mm.Hg (and in 3 it was 180) and of these only 2 are still alive one year and ten months and one year and one month after the operation; but one man with diastolic pressure of 180 lived for two years and two months after the operation. Amongst the 19 women, 5 had a diastolic pressure of 150 or over (maximum 160) and only one has died (an operation death). The height of the blood-pressure and its range shows no marked difference in the two sexes. In the group with renal hypertension the diastolic pressure ranged from 115 to 160.

In assessing the value of the operation, the effect on the blood pressure, on the headaches, on the fundi, and on general health will now be considered. There were 12 males with essential hypertension who survived the bilateral operation; in 8 the blood-pressure was not appreciably altered although survivals occurred to over two and four years; in 3 there has been a slight to moderate lowering and in 1 patient the pressure has been maintained at normal for four months. In the 17 females who survived the operation the pressure has been unchanged in 6 (survival up to three years ten months) there has been slight to moderate lowering in 5, and marked improvement in 6. In the group of renal hypertension the blood-pressure improved in 3, and has remained unaltered in 4. In all cases the record of the blood-pressure is the latest, and follow-up records show that although for a varying period after operation the pressure may be much reduced, as time passes it reverts more closely to its original figure. Headache has been greatly benefited in almost every case. Thus of 10 men in whom it was severe it has been abolished in 5, and much improved in 2, and in each of 13 women with severe headache it has been greatly reduced. In the 7 patients with renal hypertension, headache has been greatly improved in 6. The optic fundi were usually dramatically improved by operation, the papilloedema subsiding with consequent gain in visual acuity and exudates and hæmorrhages becoming absorbed. Changes of this nature occurred in 7 out of 12 male survivors (though 2 of these relapsed later), and in each of 11 women with essential hypertension, and in each of 5 patients with renal hypertension. General health and residual disability are not easy to assess but there is no doubt of the return of a sense of well-being, of physical and mental energy and endurance in many of the patients. In approximately half of the men and of the women there has been improvement of a worth-while degree—one man in particular worked very energetically for over four years. In the patients with renal hypertension, 5 of the 7 have shown improvement, the other 2 being still convalescent.

I would like now to direct attention to the 8 deaths following operation. Of these, two followed the lesser or Adson procedure and 6 the more extensive or Smithwick denervation. The ratio (1 : 3) is roughly the same as for the numbers of the two operations (10 to 36) so that although the Smithwick operation is undoubtedly the more severe it has not been followed by a heavier mortality rate. Admittedly the numbers are small for any generalization, and in the course of time we have learnt to reject cases which earlier might have been subjected to operation. Although these deaths are rightly ascribed to the operation, the manner of death shows that operation for the most part has but accelerated the morbid processes. In half, death was due to uræmia, although in one it was probably aggravated by a severe wound infection; a fatal outcome in these patients might well have been expected, for in 3 the pre-operative blood urea was 94, 106, and 125 mg. per 100 c.c. of blood respectively, and we have learnt not to operate on such cases. In the other case dying of uræmia, the pre-operative blood urea was only 56 but other routine tests showed a severe impairment of renal function. Two deaths occurred from heart failure, and in these the pre-operative blood-pressures were 300/180 and 230/180 respectively. There was one death from cerebral hæmorrhage five days after the first stage. The other death is ascribed to cerebral anoxia from hypotension; the blood-pressure steadily fell during the operation (second side) to a final reading of approximately 75, and a variety of resuscitative methods could not maintain it above 100 systolic for more than a few minutes at a time; after an initial recovery of consciousness when the anæsthetic was withdrawn, the patient passed into deep coma, areflexia, and hyperpyrexia of 106°, dying some fifteen hours after the operation. Necropsy confirmed the part played by anoxia. The pre-operative blood-pressure was not particularly high (220/130).

In attempting to assess the risk of operation in any particular patient, it is helpful to refer to the analysis of papilloedema, headache, and impairment active or past of cerebral, cardiac and renal functions (Tables II A and B). Operative deaths have occurred for the most part in those patients who presented with all five, or four out of five of these features, the women not scoring quite so high as the men (and they also carry a lower operative mortality). Those patients who survived the operation for the most part presented fewer of these features, i.e. only one scored the maximum 5 and only 3 scored 4, the rest scoring 3's or less. Therefore, in any particular case of essential hypertension, operation might well be refused if all five major manifestations are present, and certainly if the renal function is severely impaired;

a high blood urea of the order of 100 mg. per 100 c.c. of blood can be regarded as a single and unequivocal contra-indication to operation even if, in other aspects, the disease appears relatively light. But this last statement does not hold good for hypertension supervening on chronic nephritis, in which the body has apparently acquired some tolerance to the impaired renal excretion.

I have abandoned the subdiaphragmatic for the thoraco-abdominal operation for two main reasons. In the earlier cases in which the lesser denervation was carried out, the characteristic symptoms of postural hypertension were not encountered although blood-pressures were not then recorded in both the recumbent and the erect postures. This phenomenon is fairly frequent immediately after the Smithwick operation, denoting a more widespread territory affected by the denervation. Whatever may be the precise cause, whether the formation of a large somatic and splanchnic pooling of blood, or whether due to a diminished cardiac input, this more widespread denervation seems to offer a greater potentiality for reducing the blood-pressure, even though the effect is found to diminish with the passage of time. This appears to me to be one good reason for preferring this operation. My other reason is anatomical; it is difficult, if not fortuitous, to effect a complete splanchnic denervation from below the diaphragm. I have found that the great splanchnic nerve and the upper lumbar ganglia can be resected in a consistently thorough manner; but resection of the lesser and least splanchnics and of other variants in the sympathetic pathways is quite unreliable from below the diaphragm; whereas removal of their respective ganglia of origin ensures their severance. Anatomical studies by Sheehan and others have shown that the sympathetic system is liable to much variation in its details, and that residual pathways may frequently be the cause for relapse in conditions other than hypertension which are treated by sympathectomy. Therefore, to ensure that the splanchnic denervation is anatomically complete, the ganglionic chain must be removed in its entirety for a distance which includes that part which is liable to give off small known and unknown branches. In my opinion this is the most convincing argument in favour of a thoraco-abdominal approach, which affords adequate access for resection of the splanchnic nerves and of any other branches seen, and of the chain in continuity from T9 to L2 inclusive. Removal in continuity is important for, if the chain breaks, it is difficult subsequently to identify and to remove T12 and L1 ganglia, which are hidden under the diaphragm. It is recommended that the diaphragm be divided radially, but I find this unnecessary, and disadvantageous owing to the difficulty I have experienced in suturing it securely, as the sutures so easily tear out. Instead, I increase access into the thorax by removing the posterior few centimetres of the eleventh as well as the twelfth rib. This also allows a higher approach in the thorax, enabling the ninth thoracic ganglion to be exposed with certainty. I have found it unnecessary in most cases to divide the intercostal nerves; these can be preserved and do not usually obstruct the view, provided the musculovascular bundle is divided; I think intercostal neuralgia is less frequent if the nerves are preserved. A manœuvre described by Professor Paterson Ross, which facilitates the exposure and removal of the chain at the level of the twelfth thoracic and first lumbar ganglion, is to trace the lumbar chain upwards, splitting the crus over it for a few centimetres, and thus allowing proper identification of the chain and of its rami. The latter may run here for part of their course in an almost vertical direction, and it is easy to pursue a ramus in mistake for the main chain, and thus to lose the ganglion. An interval of at least two weeks has been allowed between sides, and often longer; delay has been occasioned most frequently by a pleural effusion, which though not mentioned in the literature so far as I am aware, has been the commonest post-operative complication, occurring after either side. These have been sterile (except in one case where it became infected from a wound infection) and have sometimes needed repeated aspiration before resolution. (In one patient the effusion persisted after many aspirations, and did not finally resolve until after the second operation.) Breathing exercises have, of course, been employed as a routine measure. In all cases I have assiduously attempted to avoid puncturing the pleura, not always successfully, because I have found that the operation is so much easier if the pleura sinks away with the lung. We have tried a variety of anaesthetics; the basis of all has been gas and oxygen with the support of pentothal, of cyclopropane, of curare, of a paravertebral block, and of a spinal analgesic. The ideal anaesthetic gives complete relaxation, quiet breathing so that the lung and pleura fall away, good oxygenation (for most of these patients have impaired cerebral circulation with little if any margin for anoxia), and avoidance of too sudden or too profound a fall of blood-pressure. I have found that shock or vascular hypotension rarely occurs at the first operation, but may be very severe at the second. Moreover, Dr. J. H. T. Challis and Dr. B. Kenton who have given most of these anaesthetics have noticed that during the operation on the second side, a fall of blood-pressure, sometimes of dramatic suddenness, is likely to occur when the identification and dissection of the splanchnics and sympathetic chain are commenced, or when they are cut. We have found that the best anaesthesia is provided by gas and oxygen with pentothal or with curare, the anaesthetist

controlling respiration during the intrathoracic dissection—this is a great help when stripping the pleura. In the more ill cases the splanchnic and the sympathetic chain can with benefit be infiltrated with local anæsthetic before starting the dissection. Spinal analgesia has been abandoned at any rate for the second side owing to the profound fall of blood-pressure which it is likely to cause. Severe hypotension at the second operation appears to be a potentially dangerous complication, and if it does not rapidly improve by raising the foot of the operating table and later of the bed vigorous measures should be taken to combat it.

I would like to record my gratitude to Professor Clifford Wilson and to Dr. Horace Evans for much of what I have learnt concerning hypertension, and for their helpful advice in these cases and in the preparation of this paper; and to Drs. J. R. Bolton and J. R. Ellis, Medical Unit First Assistants, for their help in analysing the case records.

Mr. F. A. d'Abreu: The discussion on hypertension held in the Section of Medicine in April 1947 (*Proc. R. Soc. Med.*, 40, 773) showed, I feel, that no method of treatment was generally agreed upon by surgeons or physicians. It is necessary, therefore, that surgical methods should be given careful testing under controlled conditions in investigating the effect of lumbodorsal sympathectomy on the more severe types of hypertension; the criteria we have adopted are: (1) retinal hæmorrhages and exudates with retinal œdema or papilloœdema; (2) a history of hypertensive encephalopathic incidents; (3) a fixed high diastolic pressure around 150.

All cases are included on one or more of these grounds. They are the ones which most urgently demand relief and have the gloomiest prognosis. They also include cases in which many authorities advise against operation and in which operation is said to give least benefit.

The report of the Metropolitan Life Insurance Company of New York, published in 1937, showed that half a million deaths occurred annually in the United States from hypertension, or at any rate from cardiovascular-renal disease with hypertension as its dominant symptom. After the age of 45 the death-rate from this disease is four times greater than that of cancer and twenty times that of tuberculosis or diabetes. Perhaps it is because the effects of hypertension are much less evident than those of cancer or tuberculosis that a more aggressive and combined attack upon the disease has not yet produced an agreed medico-surgical line of treatment. Also perhaps it is because the prognosis in each particular case of essential hypertension is unsure. The same reason cannot, however, be advanced in cases of the severe degrees of hypertension. Here, once the diagnosis is made, a fatal outcome is certain within five years and the vast majority will be dead in two years. Keith, Wagener and Barker followed up 146 malignant hypertensives on medical treatment alone and only one survived for five years.

In spite of the fact that Peet reported 19% of his malignant cases alive between five and eleven years after operation, it is this very group which so many authorities regard as being unsuitable for operation.

The horrors of the grave forms of hypertension are hard to exaggerate. The severe headaches, the rapid onset of blindness and an early and certain death with severe pain would, one might imagine, demand that every means should be taken to relieve the condition. If surgery can offer an alleviation of symptoms without certain proof of prolongation of life, it is clearly justified, if the operation carries with it no prohibitive mortality. If prolongation of life be attained the justification is even more evident.

The series of cases reported here is an attempt to examine the effect of sympathectomy in the different groups. It is important in the first place to define what one means by malignant hypertension as there appears to be some lack of agreement as to what constitutes malignancy. It has been said that one can only recognize it by the length of time which elapses between the onset of symptoms and death.

Recognition may be made on the following: (1) Sudden onset of gross hypertension in a previously normal patient. (2) Rapid progress of the disease. (3) A fixed high diastolic pressure. (4) Angiospastic retinitis with hæmorrhages, exudates and retinal and papillary œdema. (5) Cardiac and renal impairment.

The best cases to deal with are those with malignant hypertension and retinitis before cardiac and renal function are both significantly impaired. The word papilloœdema should, we feel, be reserved for cases with a space-occupying lesion within the skull. Retinal œdema, which may or may not involve the papillary area, is the sign which points out the gloomiest prognosis.

I hope to show in this small series of cases that operation should be performed in every case of the worst form of hypertension if severe kidney damage has not yet occurred. The

a high blood urea of the order of 100 mg. per 100 c.c. of blood can be regarded as a single and unequivocal contra-indication to operation even if, in other aspects, the disease appears relatively light. But this last statement does not hold good for hypertension supervening on chronic nephritis, in which the body has apparently acquired some tolerance to the impaired renal excretion.

I have abandoned the subdiaphragmatic for the thoraco-abdominal operation for two main reasons. In the earlier cases in which the lesser denervation was carried out, the characteristic symptoms of postural hypertension were not encountered although blood-pressures were not then recorded in both the recumbent and the erect postures. This phenomenon is fairly frequent immediately after the Smithwick operation, denoting a more widespread territory affected by the denervation. Whatever may be the precise cause, whether the formation of a large somatic and splanchnic pooling of blood, or whether due to a diminished cardiac input, this more widespread denervation seems to offer a greater potentiality for reducing the blood-pressure, even though the effect is found to diminish with the passage of time. This appears to me to be one good reason for preferring this operation. My other reason is anatomical; it is difficult, if not fortuitous, to effect a complete splanchnic denervation from below the diaphragm. I have found that the great splanchnic nerve and the upper lumbar ganglia can be resected in a consistently thorough manner; but resection of the lesser and least splanchnics and of other variants in the sympathetic pathways is quite unreliable from below the diaphragm; whereas removal of their respective ganglia of origin ensures their severance. Anatomical studies by Sheehan and others have shown that the sympathetic system is liable to much variation in its details, and that residual pathways may frequently be the cause for relapse in conditions other than hypertension which are treated by sympathectomy. Therefore, to ensure that the splanchnic denervation is anatomically complete, the ganglionic chain must be removed in its entirety for a distance which includes that part which is liable to give off small known and unknown branches. In my opinion this is the most convincing argument in favour of a thoraco-abdominal approach, which affords adequate access for resection of the splanchnic nerves and of any other branches seen, and of the chain in continuity from T9 to L2 inclusive. Removal in continuity is important for, if the chain breaks, it is difficult subsequently to identify and to remove T12 and L1 ganglia, which are hidden under the diaphragm. It is recommended that the diaphragm be divided radially, but I find this unnecessary, and disadvantageous owing to the difficulty I have experienced in suturing it securely, as the sutures so easily tear out. Instead, I increase access into the thorax by removing the posterior few centimetres of the eleventh as well as the twelfth rib. This also allows a higher approach in the thorax, enabling the ninth thoracic ganglion to be exposed with certainty. I have found it unnecessary in most cases to divide the intercostal nerves; these can be preserved and do not usually obstruct the view, provided the musculovascular bundle is divided; I think intercostal neuralgia is less frequent if the nerves are preserved. A manoeuvre described by Professor Paterson Ross, which facilitates the exposure and removal of the chain at the level of the twelfth thoracic and first lumbar ganglion, is to trace the lumbar chain upwards, splitting the crus over it for a few centimetres, and thus allowing proper identification of the chain and of its rami. The latter may run here for part of their course in an almost vertical direction, and it is easy to pursue a ramus in mistake for the main chain, and thus to lose the ganglion. An interval of at least two weeks has been allowed between sides, and often longer; delay has been occasioned most frequently by a pleural effusion, which though not mentioned in the literature so far as I am aware, has been the commonest post-operative complication, occurring after either side. These have been sterile (except in one case where it became infected from a wound infection) and have sometimes needed repeated aspiration before resolution. (In one patient the effusion persisted after many aspirations, and did not finally resolve until after the second operation.) Breathing exercises have, of course, been employed as a routine measure. In all cases I have assiduously attempted to avoid puncturing the pleura, not always successfully, because I have found that the operation is so much easier if the pleura sinks away with the lung. We have tried a variety of anaesthetics; the basis of all has been gas and oxygen with the support of pentothal, of cyclopropane, of curare, of a paravertebral block, and of a spinal analgesic. The ideal anaesthetic gives complete relaxation, quiet breathing so that the lung and pleura fall away, good oxygenation (for most of these patients have impaired cerebral circulation with little if any margin for anoxia), and avoidance of too sudden or too profound a fall of blood-pressure. I have found that shock or vascular hypotension rarely occurs at the first operation, but may be very severe at the second. Moreover, Dr. J. H. T. Challis and Dr. B. Kenton who have given most of these anaesthetics have noticed that during the operation on the second side, a fall of blood-pressure, sometimes of dramatic suddenness, is likely to occur when the identification and dissection of the splanchnics and sympathetic chain are commenced, or when they are cut. We have found that the best anaesthesia is provided by gas and oxygen with pentothal or with curare, the anaesthetist

TABLE III							
	Age	Sex	Duration of symptoms	Pre-operative B.P.	Interval	Post-operative B.P.	Post-operative course
T. E. ..	30	M.	7 months	205/135	6 months	180/135	Symptomless; no evidence of cardiac failure. Doing full work
T. G. A...	40	M.	3 months	260/160	5 months	170/125	Working hard—probably too hard. Symptomless
R. N. ..	42	M.	3 weeks	260/150	6 months	200/130	Symptomless
J. H. ..	48	M.	Hypertension known for 15 years. Symptoms for one year	210/120	5 months	110/80	Symptomless but tires easily
K. M. ..	25	F.	Headache for 5 years. Blurring of vision for 2 months	230/155	4 months	195/125	Vision improved. Has returned to work
E. C. ..	29	M.	5 months	210/145	3 months	200/135	Doing light duties. Symptoms much improved. Occasional mild temporal headache
H. C. ..	47	M.	6 weeks	250/150	1 month	230/160	Died 11 weeks after second operation
W. D. ..	34	M.	2 years	250/150	6 weeks	170/130	Residual left visual defect. Occasional mild left-sided headache

Mr. King, the ophthalmic surgeon, very kindly examined all cases before and after operation and his reports on the fundi are given in Table IV:

TABLE IV			
	Pre-operative ophthalmic examination	Time interval	Post-operative ophthalmic examination
T. E. ..	Fundi: Veins congested and compressed by arteries at crossways. Many soft exudates along course of vessels. Only a few punctate hæmorrhages. Some retinal œdema. Well-marked hypertensive retinitis of grave general significance	3 months	The improvement in this man's fundi is striking—(a) all the recent soft exudates have disappeared; (b) the few small hæmorrhages have absorbed; (c) the venous congestion and retinal œdema are definitely less; (d) the small more chronic exudates near the optic disc in the right eye are smaller and less numerous
T. G. A...	Left fundus: Disc normal. Small white exudates between disc and macula. One cotton-wool patch along left infero-temporal vessels. Right optic disc not well seen. No papillœdema	6 months	Fundi normal
R. N. ..	Extensive hæmorrhages and exudates in right eye. Some hæmorrhages and exudates in left eye. Marked hypertensive retinopathy with thrombosis of inferior temporal vein	7 months	Improvement in the fundi is dramatic. On the right side there are exudates still present near the optic disc and one tiny hæmorrhage to the inner side of the optic disc. On the left side there are no exudates seen but two very small hæmorrhages along the superior temporal artery. There is sclerosis of arteries and veins
J. H. ..	Not seen by Mr. King		Not seen by Mr. King
K. M. ..	Both fundi show (a) tortuosity of vessels; (b) venous congestion; (c) diffuse retinal œdema; (d) a number of large exudates; (e) a few small hæmorrhages. This is a classic hypertensive retinitis	4 months	The improvement in the fundi is striking. The only pathological changes remaining are slight œdema most marked at the right fovea and a few points of exudate

prognosis in the untreated case of lesser degrees of essential hypertension is largely uncertain in each particular individual although there is a great deal of evidence, according to Peet, Smithwick and others, that the average expectation of life is appreciably lengthened by sympathectomy. The selection of cases in this group is important, and tests by sedation or epidural block show that some cases will not benefit by the operation.

In the group of severe cases treated by us none has been excluded whatever may be the result of sedation tests. All have received great benefit except one case who was submitted to operation when he was going blind and had very severe renal damage. He stood the operation well and said he felt better. This was the only case, however, in which no improvement in the fundi was seen. He left hospital but was readmitted some months later and died of cardiovascular-renal failure, having been almost completely blind for a month before his death.

All the cases have been treated by a team consisting, first, of a physician. Most of the cases were very fully assessed by Sir Arnold Stott and Dr. S. P. Meadows at the Westminster Hospital and reassessed after operation by them. The assessment by a physician is important for many obvious reasons and also has the advantage that a true and unbiased picture of the value of the operation may be formed. Another important member of the team has been the ophthalmic surgeon, Mr. E. F. King, who in every case but one reported on the fundi before and after operation and has provided us with paintings of the fundi [shown at the meeting]. The anaesthetist, Dr. G. S. W. Organe, has discovered, by careful investigation of the patient under anaesthesia, some interesting facts about the disease. A careful follow-up is, of course, essential.

All our cases, except the one mentioned above, who was, I must admit, treated somewhat experimentally to determine the degree of renal impairment beyond which the irreversible change occurred, have returned to work and are asymptomatic. The series, though small, ranges between the ages of 25 and 48 and there has been no operative mortality. These two facts make us feel certain so far that there can be no question of the value of sympathectomy in the most serious forms of hypertension.

The Smithwick type of sympathectomy has been used in all, fulfilling what we regard as the minimal excision, i.e. from T8 to L1 at least, on each side, with excision of the coeliac ganglion and the greater, lesser and least splanchnic nerves as high up as possible. This operation is safe and no severe complications have occurred post-operatively. It is pre-ganglionic and although the sympathetic chain cannot be removed at as high a level as by the transthoracic route, a very full and complete excision of the coeliac ganglion is done and by excision of the eleventh as well as the twelfth ribs, the sympathetic chain can be removed as high as T7. The higher level, which can be reached by the transthoracic route, is not absolutely necessary as far as the splanchnic nerves are concerned as these are only relayed in the sympathetic chain, their ganglion being the coeliac. Another advantage of the Smithwick approach is that the kidney can be fully explored, tumours of the suprarenal excluded and all the sympathetic filaments to the adrenal gland removed also. A biopsy of the kidney can be made when required.

The dissection is extrapleural and the only post-operative complications have been pleural effusions which, except in two cases, have been minimal. In two cases also there has been severe referred neuralgic pain into the loins and inguinal regions. This pain has always cleared up in a fortnight at most and has always been helped by getting the patient up.

All cases are subjected to the following pre-operative investigations:

TABLE I.—ROUTINE PRE-OPERATIVE INVESTIGATIONS

- | | |

The preliminary results of operation may be seen from a study of the following summary of the cases. The pre-operative blood-pressure was taken after a period of rest in bed and the post-operative blood-pressure was taken with the patient lying down on a couch when attending as an out-patient (Table III).

cutaneous area of anhidrosis by means of an extremely sensitive electro-dermatohmeter designed by A. H. Ratcliffe.

Fig. 3 shows the best pattern yet found and fig. 4 the worst. In each case the anatomical

removal has been satisfactory, but careful examination with the electro-dermatohmeter has revealed incomplete denervation. It is felt that unsuccessful results of sympathectomy in hypertension may be due to incomplete denervation rather than to the selection of an unsuitable type of hypertension.

Mr. A. Dickson Wright: There is no doubt that sympathectomy supplies a means of breaking the vicious circle which obtains in hypertension, and now that the operation has proved successful in the younger cases, there has been a tendency to extend the operation to greater ages than ever, 55 or 60 in selected cases, and also to practise the operation in cases with definite signs of cardiac mischief. Northfield seems to have been operating on cases which I have been in the habit of refusing as being too risky and hopeless, and seems to have salvaged some of these cases. The choice of operation is now very difficult, good results having been claimed with all of the operations. A useful clinical experiment would

TABLE IV (*continued*)

	Pre-operative ophthalmic examination	Time interval	Post-operative ophthalmic examination
--	--------------------------------------	---------------	---------------------------------------

E. C. . .	Both fundi show (a) a few soft exudates and striate hemorrhages; (b) congestion of retinal veins; (c) silver wire arteries; (d) generalized retinal oedema. A case of hypertensive retinopathy	5 months	The improvement in both fundi is marked. In both eyes all hemorrhages have disappeared and all soft exudates absorbed. There are, however, some small hard exudates above the right macula which are new. The retinal oedema is much less marked though still visible round the optic discs. The vessels are unchanged
H. C. . .	Fundi: Gross retinal oedema, exudates and hemorrhages. Swelling of optic discs not excessive. Arteries and small veins congested and irregular. Gross hypertensive retinopathy affecting particularly the optic discs, and peripapillary areas		Died eleven weeks after second operation
W. D. . .	Fundi: (1) Retinal oedema particularly around macula and optic discs; (2) sclerosis of arteries which show extreme variability in calibre; (3) veins somewhat congested and compressed by arteries at crossing; (4) a few medium "soft" exudates round macula; (5) no hemorrhages; (6) widespread anterior choroid-retinal degeneration. This no doubt is partly due to retinal vascular changes, but also to underlying sclerosis of choroidal vessels	2 months	Very considerable improvement. The arteries are still constricted but there is now no nipping of the veins. On the temporal side there are a few residual patches of exudates otherwise the retina there has returned to normal. Mild oedema on the nasal side of the disc

This series with so short a follow-up does not, as yet, advocate operation on the grounds of prolongation of life, but the fact that these seriously distressed and incapacitated people are now all, except one case, asymptomatic and back at work, convinces us of the value of sympathectomy in severe hypertension. Unless these first cases are quite abnormal we feel that one might as well refuse to remove a painful cancerous growth because ultimate cure or freedom of symptoms could not be promised, as deprive these unfortunate cases of the relief afforded by an adequate sympathectomy.

I would like to express my thanks to Sir Arnold Stott and the physicians of the hospital for the assessment of these cases and for asking me to operate on them, to Mr. King for his great help with the ophthalmoscopic aspect and to Dr. J. Harland and Mr. C. Drew, the respective medical and surgical registrars, who have done so much in keeping the records of these patients.

Professor A. M. Boyd: Surgeons perform sympathectomy for hypertension with differing objects in view. Some maintain that sympathectomy acts by producing passive dilatation over a wide area of the vascular bed with consequent decrease in peripheral resistance. Others stress denervation of the suprarenals with diminution in secretion of adrenaline or interception of vasoconstrictor impulses to the kidney as their objective.

As the cause of hypertension is still illusive, the rationale of sympathectomy must be conjectural. It is probably wise to plan a sympathectomy which will achieve all the suggested requirements. Professor G. A. G. Mitchell of Manchester, on anatomical grounds, has shown that in order to be reasonably certain of meeting these requirements, bilateral resection of the sympathetic trunks from the fourth dorsal ganglion to the third lumbar and removal of the splanchnic nerves are necessary. The fourth dorsal ganglion must be removed in order to be certain of including the para-aortic nerves (Mitchell). The third lumbar ganglion should be included in order to remove contributions from this ganglion to the renal plexus (fig. 1).

I have carried out this procedure since January 1947. The twelfth dorsal ganglion to the third lumbar are removed through an oblique muscle-cutting incision in line of the twelfth rib, part of which is resected. The upper segment and thoracic splanchnics are removed transpleurally, access being gained by resection of the eighth rib (fig. 2). An attempt has been made to estimate the completeness of the operation by careful mapping out of the

President—G. E. VILVANDRÉ

[February 13, 1948]

? **Gummatous Ulceration.**—J. H. B. URMSTON, M.R.C.S., L.R.C.P. (for T. W. MIMPRISS, M.S.).

E. L., aged 53, presented as a case for diagnosis.

She has noticed a "lump" on the face for three years. Healthy, has never been abroad; had two miscarriages and has one son aged 23 alive and well.

History of three years' duration—difficult to obtain. Three years ago had an ulcer of cheek which spread destroying the right orbit. This was followed by a swelling which descended from her forehead. She has no other complaints and has had, until reporting to hospital three weeks ago, no treatment whatsoever.

On examination she has an œdematous swelling arising from the upper lid of the right eye, the size of an orange. The right cheek was perforated by various sinuses discharging yellow pus—the right eye was not visible. There was scarring over the front of the neck, presumably where the process had healed.

Nothing else relevant in general examination was discovered.

Special investigations.—W.R. ++. Kahn +. Urine: Albumin a trace.

On microscopy of discharge from lesion—no lepra cells or mycelia seen.

X-ray of skull: Evidence of basal sclerosing osteitis.

Mr. Mimpriss: The scarring on the left-hand side and front of the neck shows that healing has occurred in places. This, in my opinion, excludes the possibility of a malignant process. The scarring here is typical of a healed gummatous ulcer.

There is no further clinical evidence to support this diagnosis but an X-ray of the skull shows a change in the base which is compatible with a gummatous osteitis. The serological tests are positive and a fortnight's treatment with mercury and iodides has produced some improvement. For these reasons the diagnosis of a gummatous ulceration seems the only possible one.

Angiocardiography in the Diagnosis of Congenital Heart Disease.—K. D. KEELE, M.D.

Angiocardiograms of three cases of congenital heart disease were shown. The following is one illustrative case.

History.—M. H., a boy aged 5 years. During his first year the patient had occasional attacks of asthma, which have become less frequent. He has not been cyanosed, and has had no other symptoms. Plays games vigorously.

Examination shows a well-built boy; normal size; weight 42 lb.

Heart: Apex beat in nipple line. Systolic thrill over aortic base. Loud systolic murmur, maximal at aortic base, conducted along the carotids, and heard posteriorly on the left. B.P. 110/80.

Arteries: Femoral pulses palpable but diminished. No evidence of anastomotic vessels even on bending forward. Other systems normal.

be to re-operate on some of the Adson and Peet operative failures, and remove the ganglionic chain transthoracically, and endeavour to obtain further facts, and it is quite possible that the cervical sympathectomy obtained by the transthoracic operation, might lessen the risks of cerebral and ocular hæmorrhage, by facilitating the flow through the other branches of the aorta. The main danger of these extensive sympathectomies is a period of post-operative cerebral ischæmia, which causes neuronal damage in the brain. Great care in the early post-operative days after the second operation is essential to maintain the blood-pressure at an adequate level by intravenous saline containing adrenaline or ephedrine.

Professor Clifford Wilson: I wish to stress the importance of accurate diagnosis in patients subjected to sympathectomy. Hypertensive renal disease is traditionally a confusing subject but recent work has thrown considerable light on the natural history of the different forms of Bright's disease and has made the assessment of prognosis less uncertain. I was glad to see that the openers had all selected for sympathectomy patients with a grave prognosis. In benign hypertension the prognosis in the individual case is an unknown factor; in malignant hypertension the average duration after the diagnosis has been made by the finding of papill-œdema is one year. It is therefore impossible to estimate the value of sympathectomy in mixed series of hypertensive patients such as have been described by some American writers. In malignant hypertension the prognosis is so grave that operation is justifiable even though the percentage of successes is discouragingly low. I must, however, emphasize the importance of papill-œdema as the diagnostic sign of malignant hypertension. In Mr. d'Abreu's series this diagnostic criterion of malignant hypertension; the only fatal case was one of these. There is a tendency to regard the result of sympathectomy as a failure if the blood-pressure level does not fall appreciably. In many instances, however, the hypertension changes in quality even though it remains quantitatively unaltered; that is the malignant character of the disease, which leads to retinal changes, increased intracranial pressure, renal vascular lesions and left ventricular failure, may be modified so that the hypertension becomes relatively benign. Unfortunately this alleviation is in the majority of cases shortlived, and it is understandable that the surgeon prefers to operate on severe cases of benign hypertension, where, although the natural outcome is uncertain, the effect of sympathectomy, especially in women, is more impressive and more lasting. I am of the opinion that the attempt to break the hypertensive vicious circle is well worth while even in patients with chronic nephritis or pyelonephritis who are on the verge of renal failure. In these cases there is often a steep rise in blood-pressure before renal function tests deteriorate; operation at this point can bring about a reversal of retinal changes and, as Mr. Northfield's cases have shown, can postpone the uræmic termination. In our series these patients have proved good surgical risks even when there was moderate nitrogen retention (up to 100 mg. %).

Dr. G. S. W. Organe showed blood-pressure and pulse records of patients with hypertension undergoing Smithwick's operation under general anæsthesia. These showed violent fluctuations not seen with other patients and less marked in the less severe cases. Commonly, there was a severe fall with a narrowing of pulse-pressure—from 260/190 to 125/120 in one case and from 220/160 to 115/105 in another. He thought this of an increased pressure gradient to the brachial artery, due to spasm of arteries proximal to the elbow, rather than to a fall in the head of pressure at the centre. Intravenous injection of 200 mg. of procaine, minutes, to 210/170 in the first and to 185/150 in the second case mentioned above. If the brachial pulse-pressure fell again, it could again be improved by injection of procaine but not always as markedly as at first. In a healthy patient, whether or not he was anæsthetized, intravenous injection produced some tachycardia but not a rise in blood-pressure.

[March 3, 1948]

THE following Short Papers were read; the Honorary Editors regret that present-day exigencies of space preclude the publishing of a full report:

Crohn's Disease.—By HAROLD C. EDWARDS, C.B.E., M.S. Those taking part in the discussion were Mr. Guy Blackburn, Mr. E. G. Tuckwell, Mr. A. Dickson Wright, Mr. J. P. Hosford and Mr. E. C. B. Butler.

Obstructive Factor in Sialitis.—By B. MCN. TRUSCOTT, M.B.E., F.R.C.S. Those taking part in the discussion were Mr. E. G. Tuckwell, Mr. A. Dickson Wright and Mr. Sol M. Cohen.

Intermittent Claudication.—By R. P. JEPSON, M.B., B.Sc., F.R.C.S. Those taking part in the discussion were Mr. Peter G. C. Martin, Mr. Sol M. Cohen and Mr. J. P. Hosford.

FIG. 3.

the right pulmonary artery is seen end-on as a dense opacity within the shadow of the main artery.

(2) *Left Anterior oblique view:* Film 2 taken at 3 sec. (fig. 3). This film corresponds in timing with film 2 in the A-P view. It shows filling of the right side of the heart. The superior vena cava can be seen entering the right auricle. The shadow of the right ventricle is superimposed on that of the auricle, and probably cannot be distinguished from it in the reproduction. The main pulmonary artery, and left pulmonary artery arching backwards, are clearly seen. In this view

FIG. 4.

direct evidence of coarctation. There is no evidence of an accompanying patent ductus arteriosus.

Dr. Keele also showed a case of pulmonary stenosis and patent ductus arteriosus

Film 6 taken at 9 sec. (fig. 4) shows filling of the left auricle and ventricle. The ventricular septum is clearly seen. From its upper end the ascending aorta is seen arching forward. The innominate artery is seen coming off the aortic arch. At the commencement of the descending aorta there is a rapid spindle-shaped narrowing of the aorta with dilatation distally—

X-ray (screening): Large left ventricle. Aortic knob well seen, no evidence of rib erosion on film.

Electrocardiogram: Normal limb and chest leads.

Angiocardiogram (*see figs.*).—(1) *Antero-posterior view*: Film 2, taken at 3 sec.

FIG. 1.

Its descending branches may be seen near the left border of the heart.

(fig. 1). This film shows filling of the superior vena cava, which can be followed into the right auricle. The input tract of the right ventricle flows horizontally to the left. The output tract flows upwards completing the third part of a U-shaped curve to the pulmonary artery. The bifurcation of the pulmonary artery is seen with the right branch crossing the spine and entering the right hilar region. The left pulmonary artery, as it passes backwards, forms a dense opacity within the shadow of the main artery.

FIG. 2.

Film 4 taken at 6 sec. (fig. 2). The pulmonary veins are now filled, and are seen converging on the left auricle which forms an oval opacity in front of the vertebræ. A narrowing of this shadow to the left indicates the region of the mitral valve. To the left and below this the left ventricle can be seen. It is not clearly outlined except in its upper part, a sign of its being in systole. The large ascending aorta is clearly seen.

X-rays: Tumour in anterior mediastinum (figs. 1 and 2).

Bronchoscopy: N.A.D. Diagnostic pneumothorax. Exploratory thoracotomy (Mr. T. Holmes Sellors): Tumour in anterior mediastinum, hard and infiltrating surrounding structures to which it was densely adherent. It was inoperable. Biopsy taken. Subsequent course uneventful.

Histology: "Section shows strands of cellular infiltration between fibrous tissue. The cellular areas show very large numbers of eosinophilic polymorphs. There are giant cells with large pale vesicular nuclei and opaque cytoplasm. There are occasional giant cells with three or four nuclei.

"These appearances probably represent Hodgkin's disease in the sclerosing stage."

Splenomegaly: Tuberculoma of Spleen. Benign Hypertension.—R. W. BAZELEY, M.B., B.S. (for J. BROWNING ALEXANDER, M.D.).

F. H., male, aged 44. Has never been abroad. No previous history of illness apart from fractured left ribs in 1940.

History of present condition.—Onset December 1946 of tightness in upper abdomen and pain under left costal margin. Symptoms relieved after one week in hospital, but recurred.

8.4.47: Ruddy, healthy: weight 10 st. 10 lb. Pulse 72, regular. Heart: Apex beat fourth space, one inch outside mid-clavicular line. No murmurs. B.P. 240/100. Bulging of left lower chest and obvious bulging of left hypochondrium. Spleen: $4\frac{1}{2}$ in. below left costal margin; slightly tender on palpation. No bruit. Liver margin just palpable, but not tender.

Other systems normal.

Investigations.—Blood-count 10.4.47: R.B.C. 4,700,000. W.B.C. 11,000. Polys. 75%. No abnormal red or white cells. Sternal puncture: Marrow count within normal limits. Blood W.R. negative. Chest X-ray: Small rounded opacity continuous with left eighth rib (? old trauma). Small, well-defined circular opacity in left mid-zone, possibly a secondary, but most likely a fibrotic nodule.

Progress.—3.5.47: Barium meal: Stomach displaced to right of spleen, which produced a filling defect in greater curvature by pressure. Splenic enlargement and discomfort gradually decreased, and on 7.5.47 spleen $2\frac{1}{2}$ in. from costal margin. Weight unchanged. Patient afebrile throughout. Discharged from hospital.

December 1947: Well and working, but appetite poor. B.P. 170/110. Spleen enlarged 4 inches. Barium meal: Alimentary tract normal. Mass pressing on stomach from left. Large calcified shadow in left upper abdomen. ? calcification in (1) splenic artery aneurysm; (2) in kidney (unlikely); (3) in spleen.

Intravenous pyelogram: Control shows large calcified upper abdominal shadow. I.V.P. calcification inconstant in relation to kidney. Kidney function normal, but left slightly displaced downward. Appearance consistent with tuberculoma.

Mantoux (1 : 1,000) strongly positive.

Lieut.-Colonel A. L. Wingfield: The diminution in the size of the spleen from an estimated 6 in. to $2\frac{1}{2}$ in. suggests that the original enlargement may have been due to infarction or thrombosis. The nature of the calcification seems to support this view. The absence of other substantial evidence of tuberculosis also makes tuberculoma an improbable suggestion.

Dr. A. Elkeles: It is doubtful whether the enlargement and calcifications of the spleen in this case are of tuberculous origin. Tuberculous manifestations in the spleen are usually of the miliary type and are the result of hæmatogenous spread. Primary tuberculosis of the spleen is extremely rare. The radiograms of this case reveal two types of calcifications of the spleen, multiple calcifications scattered over the organ and a calcified ring shadow the size of a tangerine near the upper pole. The multiple areas of calcification are not well defined and are mainly of low density, which suggests that the lesions are of more recent origin. Calcified ring shadows of the spleen may be due to a calcified aneurysm of the splenic artery usually showing a double ring shadow with a gap at the

and a third case of complete heart block and patent ductus arteriosus. These cases were similarly investigated with angiocardiograms.

Technique.—The technique used for these films has been that of Robb and Steinberg with certain modifications. After preliminary tests for iodine sensitivity 15 to 20 c.c. of 70% pyelosil are rapidly injected into an arm vein. Films are exposed at injection and at intervals of $1\frac{1}{2}$ sec. for 12 sec., using 8 films in all. The rapid changing of cassettes is facilitated by the cassette-changer shown at the meeting. An exposure of $1/20$ sec. is made using 63 kvp, and 200 ma.

Comment.—Since 1939 when Mr. O. S. Tubbs and myself first embarked on ligation of a patent ductus arteriosus, I have become increasingly aware of the difficulty and importance of accurate diagnosis in acyanotic congenital heart lesions. Now that operation for coarctation of the aorta has been introduced, positive diagnosis of the lesion and exclusion of complicating or compensatory forms of congenital heart disease are even more necessary. The usual methods of clinical and radiological examination are at present unsatisfactory in this respect. The three cases shown at the meeting were selected to illustrate the value of angiocardiography in two instances of patent ductus arteriosus, one with a complicating lesion, one without, and a third case of coarctation of the aorta which is described here.

Mediastinal Tumour.—D. P. F. EMBLETON, M.R.C.S., L.R.C.P. (for N. LLOYD RUSBY, D.M.).

Mrs. E. C., aged 50. Nine months' history of asthmatic attacks, particularly at night. Cough with a little mucoid sputum. Short of breath on exertion. No loss of weight. Exacerbation of symptoms in the autumn. No past illnesses of note.

Florid complexion. No distension of cervical veins. No palpable glands. Dullness

FIG. 1.

FIG. 2.

to right of upper sternum. Heart N.A.D., B.P. 120/80. R.B.C. 4,480,000. Hb 88%. Sputum: No T.B. Urine N.A.D. Blood Kahn negative. Aschheim-Zondek test negative.

spent in hospital than out, with repeated melæna and hæmatemesis. Barium meals and blood transfusions and œsophageal dilatations punctuated his unhappy existence.

The first operation performed was a phrenic avulsion to relax the crus of the diaphragm, and no benefit resulted. The second was to open the thorax and mobilize the diaphragm into a tent and raise this above the cardia in an endeavour to prevent the loculation of the stomach into acid cardiac and alkaline pylorus portions by the diaphragm. It was noticed that the cardiac orifice was extensively scarred and stenosed, and it was dilated under vision by bougies while the chest was open. After initial improvement from this operation, he soon relapsed into his former condition and continued to deteriorate.

The third operation consisted in a resection of the scarred lower portion of the œsophagus and the cardiac two-thirds of the stomach, the dilated œsophagus was joined end to end to the pyloric third of the stomach; both vagi were of course divided as a result (fig. 2). The result eighteen months later is excellent, weight is nearly doubled, fits have disappeared, anæmia is gone and regurgitation has vanished, so that he now sleeps horizontally in bed. A great mental improvement has resulted from release from all his torments and he is able to make up for the years of education he has lost.

Temporal Arteritis (Giant-Cell Arteritis).—A. P. DICK, M.D.

Male, aged 69. Retired draper.

7.11.47: History of one year's vague aching pains in joints, and of five weeks' dull headache in left temporal region, radiating to vertex and occasionally to left ear and jaw. At same time noticed a "hard vein" in left temple. Previous health good.

On examination.—Frail elderly man. Left temporal artery prominent and did not

FIG. 1 (7.11.47).—Showing affected temporal artery.

FIG. 2.—Section of artery. ($\times 32$.)

pulsate in distal half; very slight tenderness over proximal part of artery. Right temporal artery also appeared slightly prominent. Blood-pressure 160/90, and evidence of generalized arteriosclerosis and of emphysema but no other abnormal signs. W.B.C. 25,100, polys. 78%. X-ray of skull: Osteoporosis.

origin of the aneurysm. Hydatid and non-parasitic cysts also occur. A case of a large calcified non-parasitic cyst of the spleen confirmed by operation was reported by Elkeles and James (*Brit. J. Radiol.*, 1943, 16, 59), in which displacement of the stomach to the right and downward displacement of the splenic flexure of the colon and of the left kidney were present. The origin of this cyst remained undetermined. Most authors are of the opinion, however, that trauma plays an important part in the development of splenic cysts. Dr. Browning Alexander's patient had an accident in 1940, resulting in fracture of the left lower ribs. It is feasible to assume that at the same time the patient suffered injury to the spleen with subsequent hæmorrhage. Since hæmosiderin predisposes to calcium deposits, it is likely that the multiple calcifications resulted from subcapsular hæmorrhage and the calcified cyst from liquefaction of a hæmatoma.

[March 12, 1948]

Congenital Short Œsophagus.—A. DICKSON WRIGHT, M.S.

C. C., aged 20, was prematurely born and at birth sustained a cephalhæmatoma. His tonsils and adenoids were removed at the age of 2 because of his facies and retarded development. He did not walk until the age of 6 and he was very slow to learn to speak and write.

At about the age of 18 months, epileptic fits were first observed and later it was noticed that these were very often preceded by stomach pains and vomiting. Later in life, vomiting and regurgitation at night became very troublesome, and when he was 13, anæmia became noticeable, and occult blood was present in the stools.

FIG. 1.—Pre-operative condition showed œsophagus with stricture formation.

FIG. 2.—Post-operative condition: pyloric half of stomach completely in chest and pylorus at the level of the cardiac orifice. Œsophagus still remains dilated, but the food passes easily into the stomach.

At the age of 14, an X-ray showed a congenitally short œsophagus which had been missed in previous X-rays. The œsophagus was dilated above a stenosed cardiac orifice, about one-third of the stomach being in the thorax (fig. 1). The lower end of the œsophagus also showed a small ulcer crater. The observation was made at this time that after the stomach had been filled with barium in the standing position, and then the patient lay down, a large amount of the meal refluxed into the œsophagus.

From then on life became progressively more miserable for him. Even with the most carefully chosen food, each meal was a battle, and he could not lie down to sleep, because of the regurgitation. The fits became more frequent. More time was

spent in hospital than out, with repeated melæna and hæmatemesis. Barium meals and blood transfusions and œsophageal dilatations punctuated his unhappy existence.

The first operation performed was a phrenic avulsion to relax the crus of the diaphragm, and no benefit resulted. The second was to open the thorax and mobilize the diaphragm into a tent and raise this above the cardia in an endeavour to prevent the loculation of the stomach into acid cardiac and alkaline pylorus portions by the diaphragm. It was noticed that the cardiac orifice was extensively scarred and stenosed, and it was dilated under vision by bougies while the chest was open. After initial improvement from this operation, he soon relapsed into his former condition and continued to deteriorate.

The third operation consisted in a resection of the scarred lower portion of the œsophagus and the cardiac two-thirds of the stomach, the dilated œsophagus was joined end to end to the pyloric third of the stomach; both vagi were of course divided as a result (fig. 2). The result eighteen months later is excellent, weight is nearly doubled, fits have disappeared, anæmia is gone and regurgitation has vanished, so that he now sleeps horizontally in bed. A great mental improvement has resulted from release from all his torments and he is able to make up for the years of education he has lost.

Temporal Arteritis (Giant-Cell Arteritis).—A. P. DICK, M.D.

Male, aged 69. Retired draper.

7.11.47: History of one year's vague aching pains in joints, and of five weeks' dull headache in left temporal region, radiating to vertex and occasionally to left ear and jaw. At same time noticed a "hard vein" in left temple. Previous health good.

On examination.—Frail elderly man. Left temporal artery prominent and did not

FIG. 1 (7.11.47).—Showing affected temporal artery.

FIG. 2.—Section of artery. ($\times 32$.)

pulsate in distal half; very slight tenderness over proximal part of artery. Right temporal artery also appeared slightly prominent. Blood-pressure 160/90, and evidence of generalized arteriosclerosis and of emphysema but no other abnormal signs. W.B.C. 25,100, polys. 78%. X-ray of skull: Osteoporosis.

Course.—17.11.47: Admitted London Hospital. Now no tenderness over temporal artery. He ran an irregular fever, and repeated blood-counts showed a persistent leucocytosis varying between 15,000 and 22,000 with polymorphs. about 80%. A few days after admission he became progressively more drowsy and disinterested in his surroundings, and slight mental confusion persisted for the next fourteen days. 24.11.47: Lumbar puncture: normal C.S.F. pressure and content. Repeated blood cultures negative; Widal reaction and W.R. negative, and a further lumbar puncture showed no abnormality. Sedimentation rate varied between 25 and 32 mm. in one hour. X-ray of chest clear. 28.11.47: Slight bilateral ptosis and weakness of conjugate upward deviation of the eyes for one day. 1.12.47: Unable to pass water and had to be catheterized for the next eighteen days. Prostate slightly enlarged but soft rubber catheter passed easily. His urine contained a cloud of albumin throughout. Blood urea 63 mg.%. Treated empirically with 30,000 units intramuscular penicillin three-hourly from December 2 to 18. By 8.12.47 had become less drowsy and confused. 10.12.47: Biopsy performed on left temporal artery.

Microscopic examination.—Degeneration of media with some infiltration with round cells and plasma cells, infiltration of the adventitia with round cells and a ring of giant cells in the outer part of the media. Gross hypertrophy of the intima almost occluding the lumen.

Following the biopsy he ceased to complain of headache and after 25.12.47 he had only slight occasional fever. His general condition improved gradually. 8.1.48: Discharged. 5.3.48: Again complaining of slight headache in left temporal region for few weeks. W.B.C. 8,300, polymorphs. 80%. E.S.R. 20 mm. in one hour.

Comment.—This condition, which is characterized by an inflammation of segments of arteries, with thrombosis, is probably much less rare than the reported cases, less than 50, would suggest. Its curious predilection for the temporal arteries is by no means constant, and a number of cases have now been reported in which the scalp vessels have not been affected. In the absence of involvement of the scalp or retinal arteries, or of a limb artery, the clinical picture may be obscure, and it may present as a long-continued illness in elderly people, with pyrexia, and at times with cerebral complications. There was no clinical evidence of involvement of other arteries in this case, apart from his mental state and the transient ptosis which suggested that some intracranial vessels were involved.

The microscopical picture in this patient was typical of giant-cell arteritis. His improvement following the biopsy is in accordance with most previously recorded cases. The case is of interest in that the very high leucocytosis (24,000) led to the suspicion of a concealed pyogenic infection as the cause of his illness. A slight leucocytosis is the rule in this condition, and the highest figure previously recorded is 17,000 (Sproul, 1942). There is one report by Robertson (1947) of a patient with this condition being treated with penicillin, which, as in this case, had no noticeable effect. The case was also unusual in that there was only slight tenderness over the affected artery and apart from the evidence of obstruction in its distal portion, there was little difference between the temporal vessels on each side.

Section of Orthopædics

President—V. H. ELLIS, F.R.C.S.

[November 4, 1947, concluded]

Invalid Chair.—J. E. GULL (*Research Fellow in Orthopædic Appliances to the British Orthopædic Association*).

The function of this chair is to raise the occupant from a sitting to a standing position (see fig. 1).

FIG. 1.—Invalid chair designed by J. E. Gull. Latest developments include arm-rests adjustable for width, back adjustable for angle, and complete arm-chair comfort.

It was originally designed for a friend who had been totally incapable of getting out of a chair unaided since an attack of infantile paralysis eighteen years ago, yet who, when once standing up, can walk. This chair enables her to get up entirely by herself without difficulty. It would, no doubt, be of equal value in cases of paralysis, arthritis, or, in fact, any complaint which makes it difficult or impossible to get up from a chair, and is likely to make all the difference in life to those who need it.

Power is supplied from the electric mains with one 3-way switch operated by the occupant—"Up", "Off" and "Down". The machine stops itself automatically at each end of its travel.

Suitable lengths of flex are provided for attachment to light or power points, and the free end of each can be plugged into the chair socket by the occupant.

The chair is fully adjustable for height to suit individual requirements. The foot-rest is raised and lowered automatically and is adjustable for height; this also prevents the chair from moving when operated on a slope.

[December 2, 1947]

Chondroma of the First Metatarsal Bone.—DAVID TREVOR, M.S.

E. B., male, aged 36.

History.—First seen on November 4, 1946, when patient stated that he had noticed a hard swelling on the inner side of the right foot for the last three weeks.

Examination revealed a hard, painless swelling which extended across the plantar and dorsal surfaces of the foot below and above the second metatarsal bone. X-rays showed gross expansion of the first metatarsal of the right foot with thinning of the cortex and appearance of fibrocystic disease of the medulla (fig. 1).

At operation the first metatarsal bone was excised except for the head. A bone

Course.—17.11.47: Admitted London Hospital. Now no tenderness over temporal artery. He ran an irregular fever, and repeated blood-counts showed a persistent leucocytosis varying between 15,000 and 22,000 with polymorphs. about 80%. A few days after admission he became progressively more drowsy and disinterested in his surroundings, and slight mental confusion persisted for the next fourteen days. 24.11.47: Lumbar puncture: normal C.S.F. pressure and content. Five weeks later the plaster-of-Paris cast was removed. The wounds were found to be soundly healed, and it appeared the graft had taken. Her progress was then satisfactory and showed steady improvement.

She stated she had been back at work since June of this year, and had been minding a machine since then. She could use her hand for almost everything she wanted to do.

She is now awaiting operation for repair of the long extensor tendon of the thumb.

Larsen-Johansson's Disease.—GEORGE BONNEY, F.R.C.S. (for DAVID TREVOR, M.S.).

P. S., male, aged 11.

History of aching pain in both knees, worse on the left side, for the past eighteen months. Relieved by rest and made worse by exertion. Pain was bad during the winter of last year when he was playing a lot of football, was almost absent during the summer and recurred when he started playing football again this year.

Past and family history.—Nothing relevant.

Physical signs.—Tenderness of lower pole of the patella, more marked on the left side, with slight swelling in this site. No limitation of knee movements.

FIG. 1.
Right knee.

On first attendance, 26.11.47.

FIG. 2.
Left knee.

On first attendance, 26.11.47.

FIG. 3.
Right knee (25.2.48) after 8 weeks' immobilization in plaster.

X-rays show: Accessory centre of ossification at lower pole of patella; fragmentation of tibial tubercle apophysis, rather similar to changes in Schlatter's disease (figs. 1 and 2). Fig. 3 shows fusion of inferior patellar ossicle (R. knee) to rest of patella, after eight weeks' plaster immobilization.

Synovioma of Right Ankle Region.—A. W. LIPMANN KESSEL, M.C., M.B.E., F.R.C.S. (for V. H. ELLIS, F.R.C.S.).

Miss E. S., aged 38.

History of painful swelling of right ankle-joint for two months.

She gave a history of having sprained her right ankle while in the A.T.S. in 1942.

graft from the fibula of the same leg was inserted (fig. 2) and the foot immobilized in a plaster-of-Paris cast for ten weeks.

Histological section of the tumour removed showed it to be a pure chondroma with large areas of myxoid degeneration.

Comment.—The patient has made satisfactory progress and, a year after operation, he has full range of movement of his foot without any complaint whatever; he has been back at work for many months and now states that he is able to play football as well as before (see fig. 3).

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 1.—Chondroma of first metatarsal, simulating X-ray appearance of fibrocystic disease; anteroposterior view.

FIG. 2.—Excision of first metatarsal, leaving the head. Bone graft from fibula placed between head and internal cuneiform.

FIG. 3.—Ten months after bone-grafting operation. The graft has become hypertrophied and has assumed more closely the shape of the first metatarsal bone.

Compound Fracture of the Radius and Ulna with Division of Dorsal Structures of Wrist-joints.—DAVID TREVOR, M.S.

D. S., aged 42. Admitted to hospital 11.11.46.

History of having caught her right forearm and hand in a machine while at work. On examination she was found to have a skin wound completely encircling the forearm, just above the wrist-joint. There was comminution of the lower end of the radius, a fracture dislocation of the lower end of the ulna, the proximal carpal joints were opened, all extensor tendons were severed, the flexor carpi ulnaris tendon was severed, the medial nerve was intact, the ulnar nerve was also intact, the radial nerve was severed at the wrist, but the bulk of the flexor tendons were intact.

At operation the same day the lower ends of the radius and ulna were brought together. Some dead muscle was excised and the skin sutured. Plaster of Paris was applied.

On 21.11.46 the fracture was manipulated, and re-manipulated on December 9. The position was then found to be fairly good and the wound had healed by first intention.

On 27.1.47 a free tendon graft was taken from the tendon of palmaris longus, and this was inserted between the cut ends of the extensor tendons. $1\frac{1}{2}$ in. of the lower end of the ulna was excised at the same time. The wound was closed and plaster of Paris applied.

When admitted to hospital about six weeks after her first attendance at the Out-Patient Department, pulsation of the tumour became evident.

Subsequent X-rays revealed a progressively destructive lesion in the region of the lateral malleolus as well as rapidly increasing general decalcification (figs. 1A and B and 2A and B).

A below-knee amputation was carried out, and the pathological report established the diagnosis that the tumour was a synovioma.

The most recent chest X-ray (January 1948) shows opacities very suggestive of early metastatic tumour deposits.

FIG. 3.

FIG. 4A. $\times 124$.

FIG. 4B. $\times 477$.

Pathology (Dr. R. H. Hepinstall).—The specimen (fig. 3) shows a soft friable tumour mass, mainly white in colour but with numerous hæmorrhagic areas, invading the lateral malleolus, talus and calcaneus. The latter is completely filled with growth and the bone is thinned and deficient in places. There is a close relationship between the tumour and the peroneal tendon sheaths, suggesting a possible site of origin.

Microscopically the main part of the tumour consists of spindle-shaped cells with scanty stroma, within which are clefts and larger spaces lined by tumour

This was treated by some form of injection (presumably novocain, but no details have been traceable). She was fit for duty after one week and had no further trouble apart from occasional twinges in her ankle, until June 1947, when she again twisted her ankle. She was treated by her own doctor with ointments and massage for a sprained ankle. Since that time pain has persisted and swelling of the ankle has gradually increased. There was no noticeable loss of weight or impairment of general health.

On examination.—Healthy-looking young woman. General examination revealed no significant abnormality. R. ankle: Irregular, soft, doughy mass about 4 in. in diameter and occupying the whole of the external malleolar area. The malleolus itself is not palpable. Definite pulsation can be elicited but there is no bruit audible on auscultation and the mass cannot be emptied by pressure.

FIG. 1A. 23.9.47.

FIG. 1B. 23.9.47.

FIG. 2A. 24.11.47.

FIG. 2B. 24.11.47.

Discussion.—When first seen, the swelling appeared to be confined to the peroneal tendon sheaths. An X-ray showed some general osteoporosis, more marked in the external malleolar area. The provisional diagnosis of tuberculous tenosynovitis was made with some confidence. However, investigations (X-ray chest: No evidence of T.B., Mantoux 1 : 1,000 negative, and E.S.R. 10 mm./hr.) were all against this diagnosis.

Costo-clavicular Compression Following Fracture of Clavicle.—J. S. BATCHELOR, F.R.C.S.

This patient, a woman aged 38, sustained a fracture of the left clavicle in June 1946 and ever since this injury has complained of pain in the shoulder radiating down the arm into the ulnar border of the forearm and hand.

Examination shows malunion of the fracture with considerable dropping of the shoulder-girdle (fig. 1). There is wasting of all the muscles of the left arm, the hand

FIG. 1.

is cold and the left radial pulse is diminished in volume compared with the right. Symptoms appear to be due to costo-clavicular compression as a result of malunion of the fracture.

Congenital Dislocation of the Shoulder.—E. HENRIETTA JEBENS, F.R.C.S.

I. B., a girl aged 16.

Complaint.—Inability to put her right hand behind her head, to her mouth or behind her back. Unable to lift anything heavy.

FIG. 1.

FIG. 2.

History.—Forceps delivery, but no signs of trauma to the child. A few days after

certain areas there are cell tufts containing polygonal cells, which show a tendency to grow into the clefts. Mitotic figures are numerous. The appearance is that of a highly malignant tumour of synovial cell origin (figs. 4A and B).

Bilateral Bony Ankylosis of Hip-joints.—F. A. SIMMONDS, F.R.C.S.

A. B., male, aged 20.

History.—Eight years ago acute osteomyelitis of the pelvis, resulting in solid bony fusion of both hips.

The left hip became fixed in 10 degrees adduction; neutral rotation; 20 degrees flexion.

The right hip fused in the position of 20 degrees abduction; 40 degrees external rotation; 50 degrees flexion.

The boy can now walk five miles, dance, and run up and down stairs easily. He is able to sit or stand for long periods without discomfort.

The spine and knees are strong and mobile and it is realized that such conditions are ideal for function, but it is felt that this function is better than it would have been had Nature fused his hips in the more usual position with the legs parallel.

Are we right in accepting this parallel position? Would it not give better function and split the load on the back, to have one hip flexed 20 degrees and the other 40 or 50 degrees, in conditions where it is apparent that both hips will become ankylosed.

Spontaneous Fracture of a Metacarpal.—

C. HOPE CARLTON, M.C., M.Ch.

The patient, a male aged 35, is a porter at Euston. On November 2, 1947, he was lifting a parcel weighing 30 lb. on to the rack of a railway compartment. He heard a crack and felt a pain in his hand.

X-ray examination shows an oblique fracture of the fourth metacarpal bone (*see fig.*).

He has made a normal recovery. The case is shown as the patient is certain that he did not knock his hand on the rack nor did the parcel hit it. There was no direct violence, it was spontaneous.

The patient's blood phosphorus is double the normal and his blood calcium half the normal. He appears to be in the best of health and has had no bony lesion in his life apart from this one.

Operative Prevention of Myositis Ossificans.—W. H. GERVIS, F.R.C.S.

Male, aged 28.

History.—26.12.46: Had a blow on the right thigh at football.

First seen 3.1.47. Very large hæmatoma under the right quadriceps, the type that progresses to myositis ossificans.

Operation (5.1.47).—Lateral incision and evacuation of hæmatoma.

X-ray (31.1.47) showed very slight myositis ossificans only.

Left hospital 12.2.47. Returned to full work 12.4.47.

Condition now: Full range of movement of knee; quadriceps normal.

(c) It would stimulate growth of the joint in general and of the margins of the acetabulum in particular.

(d) It would increase muscular strength and give normal muscle balance.

(e) It would allow the child to get about and so avoid the psychological damage of long and uncomfortable immobilization in plaster.

(f) It would make things much easier for both parents and surgeon.

(4) The head can only leave the acetabulum backwards. Owing to the action of the ilio-femoral band it can only go backwards if the knee goes forwards. Therefore any movement is permissible as long as the knee is kept back.

(5) The ilio-femoral band or ligament of Bigelow is the most important factor in this condition for four reasons.

(a) It is upon the fulcrum supplied by it that the head is levered into position in the usual methods of reduction. This means that the force used in pressing the knee back is multiplied about eight times in pressing the head against the rim of the acetabulum, with consequent risk of damage.

(b) The head will slip in most easily if this ligament is relaxed, as it is in the foetal position of the limb.

(c) In older cases in which reduction by manipulation is impossible, this ligament is the obstacle, and if divided the head may be pushed into place in the way described.

(d) In unreduced cases the pain and instability of the limb are mainly due to the head of the femur swinging over a wide area on the fulcrum of this ligament. Division of it may allow a stable false joint to be formed.

APPLICATION OF THE HYPOTHESES

Reduction of the deformity.—The child is laid on its face, and the dislocated thigh brought into the "foetal angle".

FIG. 1.

Through the heel of one hand, the surgeon transmits his weight with a stiff arm on to the great trochanter, while with the other he moves the knee up and down through a small angle. When the exact point of entry is reached the head should go in with a characteristic crunching feeling, often divided into two stages. The commonest error is to mistake a movement of the head forward above the trochanter for a reduction. If this occurs the head will be felt to rise and fall when the knee is moved up and down, whereas in a true reduction no movement can be detected under the palpating thumb (fig. 1).

Plastering after reduction.—To allow reactions to settle down and the muscles adjust themselves to the new position of the bones it is necessary to leave the hips in a double spica for a month. The hip is left unmoved once it is in: the temptation to demonstrate the reduction by snapping it in and out must be resisted. The child is raised face downwards by an assistant on either side grasping the legs below the knee and so raising the pelvis off the table while maintaining the utmost abduction of the thighs possible. The plaster should be strengthened by a slab over the back and junctions of the body and thighs, and should leave as wide a "nursing area" round the perineum as possible. The knee on the side of a dislocation should be included, as otherwise some degree of adduction is possible.

birth an abnormality of the right shoulder was noticed and the child taken to Guy's Hospital. Treated on an abduction splint for a few weeks.

Family.—The patient is the youngest of seven children. The father and three brothers have severe deformities of hands and feet.

On examination.—The patient holds her right arm internally rotated and slightly abducted. There is limitation of external and internal rotation and extension of the right shoulder-joint. Right elbow shows slight limitation of extension. Wrist and hand normal and grip equal to left. Wasting of right deltoid, arm and forearm muscles, but no paralysis and electrical muscle tests are all normal. Right scapula higher than left and slightly smaller. There is a subspinous dislocation of the humeral head.

X-ray: There is a backward dislocation of a deformed humeral head. The acromion process is arched downwards and the coracoid process greatly elongated (fig. 1). A rudimentary glenoid only is present and the humeral head appears to articulate with its posterior border. Upper one-third of shaft of humerus curved with convexity forwards (fig. 2—X-ray taken through joint from above downwards).

Comment.—Since R. W. Smith first recorded congenital dislocations of the shoulder-joint in 1839 21 cases, of which 8 were bilateral, have been reported in the literature. Grieg, reviewing all reported cases of shoulder dislocations in infants, in 1923 came to the conclusion that there were 3 types: viz. true congenital; obstetric; paralytic. At that date he found 10 cases of undoubted primary congenital dislocations of the shoulder of which 2 were bilateral. Since that date 11 cases (excluding the one I have now described), of which 6 were bilateral, have been reported. Scudder described 2 cases in one family and Valentin 3 members of one family with this deformity. Wolff describes a bilateral case; the grandfather, mother and one uncle of this patient had severe congenital deformities of the hands closely resembling my case. In a number of the reported cases other congenital deformities were associated with the shoulder dislocation.

The Treatment of Congenital Dislocation of the Hip

By DENIS BROWNE, F.R.C.S.

HYPOTHESES UPON WHICH THIS TREATMENT IS FOUNDED

- (1) THE hip is dislocated during intra-uterine life by a thrust upon the knee from the uterine wall sending the head of the femur backwards out of the acetabulum.
- (2) In consequence the best way to get the head back into place is to reverse the process, and with the shaft of the femur held in the same direction as when dislocation occurred, to thrust it upward and forward by pressure on the great trochanter.
- (3) Active movement of the femur, when the head is in position would have six good effects:
 - (a) It would cause atrophy by pressure of any tissues lying between the cartilage of the head and that of the acetabulum.
 - (b) It would have a "self-centring" action, which would work the head into the true centre of the socket.

Film: Curare (Intercostrin) in the Treatment of Acute Anterior Poliomyelitis

Commentary by Sir REGINALD WATSON-JONES, F.R.C.S.

A FILM by Dr. Nicholas S. Ransohoff of New York, which had been brought to this country by Sir Morton Smart, was introduced by Sir Reginald Watson-Jones. Dr. Ransohoff accepted the evidence of Plato-Schwartz that in acute anterior poliomyelitis there was widespread muscle spasm, and he believed that such spasm was responsible for dysphagia, respiratory embarrassment and early onset of deformity. By injection of curare the spasm was relieved, Sherrington's law of reciprocal innervation was re-established and the pathological stretch reflex was obliterated. The dosage employed was 0.9 unit per kilo of body-weight every eight hours for the first twenty-four hours; the dosage thereafter being increased, if there was no adverse reaction, to 1.5 units per kilo of body-weight every eight hours. Intramuscular injection was continued until all evidence of muscle spasm had disappeared.

The essential principle of Ransohoff's treatment was not simply to give curare injections, but to make use of such injections in order to institute passive stretching, exercises, weight-bearing and ambulation at the earliest possible moment. The exercises and movements were started within twenty-four hours of admission. At three separate intervals during the first three hours after each daytime dose of curare, every joint of the body was put through as complete a range of movement as possible. All muscles of the extremities, back and neck, were stretched in the attempt to re-establish normal muscle length. The patient was put on his feet as early as possible, no attempt being made to avoid physical tiredness or fatigue. Throughout the hours that joints and muscles were not being stretched the patient exercised with parallel bars, specially constructed chairs, trapeze fastened to the foot of the bed, mariner's wheels, bicycles, and every type of occupational therapy apparatus. The patients were kept busy continuously.

It was emphasized that no claim was made to have established a cure for anterior poliomyelitis, but it was believed that this treatment gave better results more quickly than by any other method. In a series of 29 patients, no fixed deformities or contractures developed. 5 patients with bulbar paralysis responded in a surprising manner to adequate doses of curare, the relief being attributed to relaxation of spasm of the accessory muscles of respiration and of the diaphragm. Dysphagia responded immediately and dramatically.

Sir Reginald Watson-Jones said that although he had introduced the film it must not be thought that he accepted Ransohoff's principles. He quoted the words of Voltaire: "I utterly disagree with what you say, but I would defend to the death your right to say it". He thought that further electromyographic investigation was needed into the question of spasm in poliomyelitis and the extent to which spasm, if it existed, was an important factor calling for special treatment. Further evidence was needed before it could be accepted that treatment by the injection of curare altered the prognosis and improved the outlook. That part of Ransohoff's treatment which insisted upon early mobilization and weight-bearing, passive stretching despite pain, and exercise despite fatigue, was in startling contrast to the principles advocated by Hugh Owen Thomas and Robert Jones. It might be that in the past we had over-emphasized the importance of protecting paralysed muscles. It might be that avoidable joint stiffness had sometimes been allowed to develop. It was possible that earlier mobilization and ambulation were advisable. But he would need much more than the evidence of this film to persuade him that fatigue and exhaustion of weak and partly paralysed muscles were desirable. Still more did he feel revulsion, amounting almost to horror, when he saw painful joints and muscles being stretched and forced despite the shouts and screams of the patient.

Maintenance of active movement within the limits laid down.—This can be managed by the device illustrated, consisting of a bar connecting two rings which encircle the thighs, and which is held against the abdomen or the small of the back by a soft belt to which it is sewn. The anterior position is the more comfortable, but the posterior gives greater abduction (fig. 2).

FIG. 2.

In this apparatus the child is allowed complete freedom to get about as it wishes. There are three main ways of progression. The first is on hands and feet, the second in the position of a Cossack dancer, with the knees bent and the buttocks near the floor, and the third is a semi-erect position with the knees widely separated.

The movement that looks most alarming, that of bringing the one leg down till the child stands upright on it, has three safeguards:

- (a) It can only bring the leg down while the other one is pointed up, with a consequent tilting of the pelvis which means that extension is much less than it seems.
- (b) This position is only possible with a strong contraction of the gluteus maximus, which pulls the great trochanter backwards and so keeps the head forwards.
- (c) The child will not put this heavy strain on the hip-joint unless it is stable; the Trendelenburg test on an unstable hip is obviously most uncomfortable.

Indications for removing apparatus.—These turn on the X-ray appearances, the willingness of the child to stand on the joint in the Trendelenburg test position, and the strength of the muscles. As a general guide it may be said that about nine months in the apparatus is an average. The children are so contented in it that there is no hurry about releasing them. When the surgeon decides the hip is stable he takes off the apparatus and allows the child to do what it will. In about three months it is walking normally.

Difficulties and setbacks.—If the hip slips out in the early stages, either in plaster or the apparatus, the treatment is simply begun again. In difficult cases one should not be afraid of forcing the knee back till it is behind the pelvis.

Results.—In the 42 cases I have treated by this method, all of them under 4 years of age, I have in all obtained stable painless hips. Some of them have slipped out once or more in the early stages but setbacks of this kind do not seem to spoil the final result. Many of the mothers report that their children "run faster than any of the other little girls".

Warning.—The apparatus described is quite unsuitable for cases that have not been reduced and plastered in the way described.

OPEN OPERATIONS.—I have tried in three older irreducible cases the division of the ilio-femoral band followed by treatment upon the lines described. The number is far too few upon which to form an opinion, but the results have been very encouraging.

REDUCTION OF AN ADULT TRAUMATIC CASE.—Without drawing any conclusions I would record that a posterior dislocation in an adult male following a railway accident was reduced with ease and speed by an intelligent but inexperienced house surgeon using the method described.

I should like to acknowledge the stimulation I have received in this work from the writings and conversation of Dr. F. Bauer (1936, *Lancet* (i), 1057).

Film: Curare (Intercostrin) in the Treatment of Acute Anterior Poliomyelitis

Commentary by Sir REGINALD WATSON-JONES, F.R.C.S.

A FILM by Dr. Nicholas S. Ransohoff of New York, which had been brought to this country by Sir Morton Smart, was introduced by Sir Reginald Watson-Jones. Dr. Ransohoff accepted the evidence of Plato-Schwartz that in acute anterior poliomyelitis there was widespread muscle spasm, and he believed that such spasm was responsible for dysphagia, respiratory embarrassment and early onset of deformity. By injection of curare the spasm was relieved, Sherrington's law of reciprocal innervation was re-established and the pathological stretch reflex was obliterated. The dosage employed was 0.9 unit per kilo of body-weight every eight hours for the first twenty-four hours; the dosage thereafter being increased, if there was no adverse reaction, to 1.5 units per kilo of body-weight every eight hours. Intramuscular injection was continued until all evidence of muscle spasm had disappeared.

The essential principle of Ransohoff's treatment was not simply to give curare injections, but to make use of such injections in order to institute passive stretching, exercises, weight-bearing and ambulation at the earliest possible moment. The exercises and movements were started within twenty-four hours of admission. At three separate intervals during the first three hours after each daytime dose of curare, every joint of the body was put through as complete a range of movement as possible. All muscles of the extremities, back and neck, were stretched in the attempt to re-establish normal muscle length. The patient was put on his feet as early as possible, no attempt being made to avoid physical tiredness or fatigue. Throughout the hours that joints and muscles were not being stretched the patient exercised with parallel bars, specially constructed chairs, trapeze fastened to the foot of the bed, mariner's wheels, bicycles, and every type of occupational therapy apparatus. The patients were kept busy continuously.

It was emphasized that no claim was made to have established a cure for anterior poliomyelitis, but it was believed that this treatment gave better results more quickly than by any other method. In a series of 29 patients, no fixed deformities or contractures developed. 5 patients with bulbar paralysis responded in a surprising manner to adequate doses of curare, the relief being attributed to relaxation of spasm of the accessory muscles of respiration and of the diaphragm. Dysphagia responded immediately and dramatically.

Sir Reginald Watson-Jones said that although he had introduced the film it must not be thought that he accepted Ransohoff's principles. He quoted the words of Voltaire: "I utterly disagree with what you say, but I would defend to the death your right to say it". He thought that further electromyographic investigation was needed into the question of spasm in poliomyelitis and the extent to which spasm, if it existed, was an important factor calling for special treatment. Further evidence was needed before it could be accepted that treatment by the injection of curare altered the prognosis and improved the outlook. That part of Ransohoff's treatment which insisted upon early mobilization and weight-bearing, passive stretching despite pain, and exercise despite fatigue, was in startling contrast to the principles advocated by Hugh Owen Thomas and Robert Jones. It might be that in the past we had over-emphasized the importance of protecting paralysed muscles. It might be that avoidable joint stiffness had sometimes been allowed to develop. It was possible that earlier mobilization and ambulation were advisable. But he would need much more than the evidence of this film to persuade him that fatigue and exhaustion of weak and partly paralysed muscles were desirable. Still more did he feel revulsion, amounting almost to horror, when he saw painful joints and muscles being stretched and forced despite the shouts and screams of the patient.

Hallux Valgus in the Adolescent

By A. ROCYN JONES, F.R.C.S.

HALLUX VALGUS is a disability that may reveal itself in early adolescence and it occurs almost invariably in females. As in the adult, the severity of the malady varies a great deal but great abduction of the big toe and a prominent bunion may occur in a patient even at 12 years of age. In the deviation of the toe the shoe plays a secondary part; many of these girls have worn footwear of good shape. The primary deforming cause is the adduction of the first metatarsal, the greater the adduction of this bone the greater the abduction of the phalanx. That a deformity of considerable severity may occur concurrently with the quickening growth of the foot in early adolescence may be due to the presence of an adduction of the metatarsal at birth which remained concealed in the smaller undeveloped foot of the young child. It is only with the greater growth of the metatarsal that the deforming influence of the shoe upon the toe becomes operative. And many patients complaining of the symptoms of hallux valgus in adult life probably derive the disability through a congenital adduction of the first metatarsal. Indeed some of these older patients declare that the deflection of the great toe and discomfort dated from their youth. It is possible that this particular metatarsal adduction is atavistic, having some morphological reference to the prehensile great toe of the higher primates.

Most of these patients are brought for advice because of pain in the great toe due to pressure on the head of the metatarsal. It is advisable to have a radiograph taken in order to determine the degree of metatarsal adduction, the amount of separation between the heads of the first and second metatarsals and the extent of the subluxation of the first phalanx if any. In the lesser degrees of adduction relief can be obtained by gentle stretching of the great toe, exercises, and splinting at night. If these measures fail then the prominence, or so-called exostosis, should be removed. In the severely adducted metatarsal, however, this procedure is not enough. But a reconstruction of the joint should not be attempted, because interference with the first phalanx is likely to damage or destroy the epiphysis, and removal of the head of the metatarsal will result in a shortened shaft with loss of effective thrust and weight-bearing by the great toe. An osteotomy of the shaft of the metatarsal in its proximal half is the better procedure and it should take the form of a modified cuneiform osteotomy whereby only part of the wedge is removed and the rest left as a spike to be impacted into the proximal segment. This device secures complete stability of the broken fragments whilst at the same time enabling angulation to take place as a means of correction of the adduction. Simple osteotomy alone is an uncertain corrective because the fragments are unstable and angulation difficult to maintain. After operation a plaster-of-Paris cast is applied from the upper calf to the ends of the toes. Gentle pressure outwards and slightly downwards on the first metatarsal head is exerted until the cast is set. The plaster is retained for six weeks after which the patient is taught exercises and mild stretching of the great toe.

The operation has only been performed where there was persistent pain whilst wearing a shoe and in every case complete relief has followed operation. It is mainly suitable for the severe type of hallux valgus where there is considerable adduction of the first metatarsal; the angulation of the fragment after osteotomy is then easier and more effective; the subluxation of the phalanx becomes automatically corrected. The great advantage in the adolescent is that the operation is entirely extra-articular. It is also applicable to adults although it has only been tried in those under 40. Older patients do not take kindly to the suggestion of having the foot for six weeks in plaster of Paris as compared with the shorter period of inactivity following reconstruction of the joint. The convalescence, however, is shorter and more comfortable after osteotomy and the joint movement is unrestricted.

FIG. 1.—A diagram indicating the steps in the operation of oblique osteotomy with impaction for the correction of severe painful hallux valgus in the adolescent. The first metatarsal is exposed in its whole length through a dorsal longitudinal incision in the skin. (1) Site and direction of osteotomy. (2) Wedge of bone required to be obliterated to produce correction of the adduction. (3) Shaded triangular area is the amount of bone actually removed by bone-cutting forceps. (4) "Spike" formed on distal segment. (5) Dotted area represents the medulla which should be broken, but not removed, by a narrow osteotome. (6) Impaction of spike into proximal segment and angulation of fragments.

R.

L.

FIG. 2.—A. S., a young adult, a radiograph of whose feet shows all the signs of a severe bilateral hallux valgus. Note the adduction of the first metatarsal, the wide space between the first and second metatarsal heads and the subluxation outwards of the proximal phalanx.

R.

L.

FIG. 3.—A. S., after the operation of oblique osteotomy with impaction. Note the correction of the adduction of the first metatarsal; the reduction of the subluxation of the phalanx; and the narrowing of the anterior half of the metatarsus as compared with fig. 2.

Cup Arthroplasty of the Hip, with Film

By G. K. McKEE, F.R.C.S.

A SERIES of 10 cases of cup arthroplasty were shown together with a film illustrating the results in four of them, and the methods employed in giving active exercises following on the lines adopted by Smith-Petersen.

The operation of cup arthroplasty is indicated in degenerative conditions of the hip-joint, particularly if bilateral, but it is important that the patients should be capable of performing vigorous physical exercises afterwards, if the best results are to be obtained.

The 2 failures.—3 cases of aseptic necrosis of the head of the femur are included, 1 a success, and the other 2 failures. The successful case is shown in some detail in the film. There is no doubt about the necrosis of the head of the femur, it arose following a dislocation. The necrosis did not involve the whole of the head, however, but only the peripheral portion. At operation, there was plenty of good healthy bone left after removing the degenerated portion. The 2 cases of aseptic necrosis where the operation of cup arthroplasty failed were sequelæ of fractures of the neck of the femur, and practically the whole head had to be removed at operation, before good bone was obtained.

Aseptic necrosis, following a fracture of the neck of the femur, is still one of the unsolved problems of orthopædic surgery. Where there is extensive degeneration of the head of the femur, a cup arthroplasty is not a satisfactory solution.

The other 8 cases.—The film shows 4 of the patients, the 3 excellent results, and 1 of the good results.

There were 4 other good results, in which the range of hip movement had been increased, the patients' activities increased, and the symptoms lessened (*see table*). In the film the patients can be seen exercising after operation, with rollers attached to their heels, running on inclined boards, so as to facilitate abduction movements in the recumbent position. The progress was followed up at intervals, and such acts as sitting, doing up their boots, cycling, walking, and even running, were gradually obtained.

The inadequacy of modern procedures.—The Whitman or Colonna reconstruction operations have never been very popular in this country, and lately the use of a metal cup, to cover the stump of the neck after removal of the great trochanter, in the Whitman type of operation, or to cover the trochanter itself in the Colonna procedure, has been tried in America, and may be useful under special circumstances, but I have no experience of them.

A subtrochanteric osteotomy of the MacMurray type, or an osteotomy combined with an attempt to obtain ischio-femoral osteosynthesis (Brittain's operation) are often employed, but obviously have many major disadvantages, of which the encasement of the patient in an enormous plaster is not the least.

Mr. McKee went on to describe a model which had been made in brass of an artificial hip-joint. This has not yet been used on a human being. It is designed to adjust itself for changes in rake and length.

The model should be made up in vitallium before trying it on the human body.

CUP ARTHROPLASTY RESULTS

Result		Indication for operation
Excellent	3 cases	2 cases of osteo-arthritis 1 case of aseptic necrosis of the femoral head
Good	5 cases	All cases of osteo-arthritis
Failures	2 cases	Both cases of aseptic necrosis

The Role of Physiotherapy in the Treatment of Poliomyelitis

By F. S. COOKSEY, O.B.E., M.D.

PHYSIOTHERAPY plays a large part in the treatment of poliomyelitis and it is expedient to review the subject after the epidemic of 1947. There are few disorders more distressing than the severe manifestations of this disease with its predilection for the younger members of the community and the extreme helplessness it may leave in its wake.

As yet there is no specific prophylactic or cure for the disease. It is not surprising therefore that promising new methods of treatment are tried sometimes with the haste which leads to exaggerated claims. We have so much to do with these patients during the stage of potential recovery that it is our special duty to maintain a critical judgment. We must sustain the confidence of patients and relatives throughout a long period of potential improvement and at the same time avoid raising false hope.

I support Seddon's view that it cannot be too strongly emphasized that no one has ever cured a case of poliomyelitis. All that we can do is to help or hinder a process of recovery that is quite outside our control (Seddon, 1947). Seddon is referring to the treatment of the disease after the virus has invaded the central nervous system. This does not preclude the possibility that future means will be found to induce immunity or arrest the activity of the virus before irreparable damage has been done. Nevertheless it is highly probable that such an advance, when it comes, will be in the laboratory. New forms of physiotherapy must be presumed to be potential weapons to assist recovery and not the means to prevent or cure the disease. At the same time we must remember that we can help Nature to localize and destroy the virus by such means as rest and heat, which is every bit as important as preventing deformity and assisting recovery of function.

We are prone to accept the diagnosis of poliomyelitis too easily. McAlpine and his colleagues investigated 104 cases admitted between August and October last year to a unit for the early treatment of poliomyelitis at the Middlesex Hospital. They arrived at the following classification:

(1) Non-paralytic poliomyelitis 24 cases; (2) paralytic poliomyelitis 26; (3) polio-encephalitis 4; (4) abortive poliomyelitis 6; (5) incorrect diagnosis 44 cases.

Thus of 104 cases admitted with a tentative diagnosis of poliomyelitis only 26 proved to have the paralytic form of the disease, although other cases showed transient paresis which cleared up spontaneously in a short time (McAlpine, Kramer, Buxton and Cowan, 1947). It is obvious that if these cases had come under the care of less critical clinicians quite erroneous conclusions might have been drawn as to the value of any particular therapeutic agent.

These figures conform to the general experience that significant paralysis occurs in less than a third of all cases. In the early stages the chances of a diagnostic error are at least as great as the risk of serious paralysis supervening.

The assessment of any therapeutic method depends first on an accurate diagnosis and secondly on the trial of a single agent in a sufficient number of cases and controls to give statistically valid results. It is difficult to carry out a scientific investigation when severe paralysis may ensue if the method on trial proves unsuccessful. In the absence of conclusive proof that a particular agent reduces the risk or severity of paralysis or deformity it is essential to rationalize treatment in accordance with fundamental principles and to avoid

accepting insufficient evidence that some method is of value and consequently to postulate theories in justification.

It is convenient to consider the disease in three stages. First, the inflammatory phase lasting from a few days to a few weeks, when treatment is directed by means of rest and heat to assist Nature to localize and arrest the infection, to relieve pain, and to prevent stiffness or deformity by prophylactic movements. Secondly, the stage of potential recovery of variable duration from a few weeks to as long as two years, when the purpose of treatment is to assist the recovery of the paralysed or weak muscles within the limits determined by the permanent damage in the central nervous system. Thirdly, the stage of chronic disability, when reconstructive operations, appliances, vocational training and the development of compensatory function in surviving muscles are employed to secure resettlement in an occupational and domestic environment suited to the residual capacity of the individual.

Physiotherapy is employed throughout the treatment of this disease, but with a different purpose at each stage. Contrast the use of heat and gentle prophylactic movements in the inflammatory phase with the carefully graduated exercise interspersed with adequate periods of rest during recovery and, again, with the strong and sustained exercise sometimes necessary to obtain adequate compensatory hypertrophy in surviving muscles for ambulation and work in the final stages. The obvious danger is that physiotherapy will be too vigorous and meddlesome in the beginning when hope and enthusiasm run high, and ineffective at the end of a long period of treatment just when it might make all the difference in the final accommodation to a permanent disability.

TREATMENT IN THE INFLAMMATORY PHASE

Poliomyelitis is no exception to the rule that rest from the onset and maintained until the infecting agent has been destroyed gives Nature the best chance to limit the damage. Ritchie Russell, in a preliminary report of his study of the effects of physical activity during the pre-paralytic stage, shows that physical activity of any kind after the onset of infection increases the risk of paralysis and that complete physical rest in bed from the onset of the pre-paralytic stage seems to protect the patient from severe paralysis (Ritchie Russell, 1947). These findings support earlier observations and the generally accepted view that strenuous physical activity coinciding with the onset of the disease increases the severity of the paralysis. But Ritchie Russell finds that the continuation of normal activity such as that of the housewife and clerk after the onset of symptoms increases the risk of severe paralysis to a considerable extent.

It seems reasonable to suppose that if ordinary physical activity is so detrimental early in the disease it may be important to disturb the patient as little as possible until the infection has subsided. I consider that it is of primary importance that we should remember that complete rest is the most effective therapeutic agent to reduce the damage done by the virus. Pain, muscle spasm and paralysis, stiffness and contracture are the result and not the cause of the disease. Treatment involving some disturbance of the patient is necessary to mitigate these secondary effects; but it is essential to do the minimum which will be effective whilst the infection is active.

Rest is attained by complete rest for the body as a whole together with efficient support for the spine and all painful and tender muscles. Of recent years rigid and prolonged splinting has been discarded in favour of minimum immobilization and early movement. As usual the pendulum has swung rather too far. Perhaps we forget that the continuous subconscious contraction of muscles to counter the effect of gravity when the part is inadequately supported does more harm than an occasional purposeful movement. A firm bed, pillows and sandbags are sufficient to rest most of the muscle groups of the trunk and limbs; but there are exceptions such as the biceps brachialis, dorsiflexors of the hand and foot, intrinsic muscles of the hand, &c., which require light plaster or plastic splints to ensure efficient rest.

In the past we emphasized the need to avoid overstretching muscles and to rest them in the relaxed position. It is now generally agreed that the optimum position is midway between contraction and relaxation. This view is borne out by the observations of Young that atrophy of muscles in experimental animals is almost as great when muscles are immobilized in the fully shortened or fully stretched position, or the sensory roots or tendon divided, as when the motor neurones degenerate. This is explained on the basis that if immobilized muscles are maintained in a position of moderate tension proprioceptive impulses stimulate the anterior horn cells and limit the wasting, whereas wasting ensues if the proprioceptive impulses are reduced by overstretching or overshortening the muscles or interrupting the afferent paths (Young, *Lancet*, 1946). We see in this experimental work justification not only for the modern practice of resting muscles in the neutral position; but also for early movements which evoke beneficial proprioceptive impulses. In the early stages, however, it is necessary to strike a balance between the value of rest for the treatment of the infection and of movement to prevent stiffness and undue wasting of muscles.

It is generally agreed that until temperature, pain and muscle tenderness have subsided rest is of primary importance and movement should be limited to what is essential to prevent stiffness. Normally one full-range movement in each direction for all affected joints once or twice a day is all that is required. The signs of active inflammation may clear up in a few days or persist for six weeks and even longer in exceptional cases. The average case takes ten to fourteen days and this is the usual time to start re-educative as distinct from prophylactic movements. The time to commence re-education is a matter of individual judgment.

The afferent impulses which we interpret as pain through connexions in the central nervous system inhibit the anterior horn cells and increase muscle wasting as well as disturbing bodily rest as a whole. Pain counteracts the beneficial effects of general and local rest and must be relieved. Heat and analgesics in the appropriate form and dosage will relieve pain; but it is our experience that the relief is of brief duration unless the painful part is rested efficiently both during exhibition of these therapeutic measures and at all other times. If heat fails to relieve pain the probability is that the method of splinting adopted whether by pillows, sandbags or plaster is inadequate. In our experience moist heat is more effective than infra-red radiation or diathermy. Applications twice or, at most, four times daily are sufficient.

In my opinion the disturbance of the patient associated with two-hourly applications of hot packs together with passive and re-educative movements to prevent so-called alienation, spasm and stiffness of muscles, as advocated by Miss Kenny and others, is liable to retard rather than assist recovery in the early stages and is probably a substantial overdose even for comparatively fit and convalescent patients. I sometimes wonder if the high incidence of muscle spasm in America compared with our experience in this country, where it is comparatively rare, is not explained by too many afferent stimuli reaching a spinal cord in an irritable state consequent upon active or recent inflammation.

We may summarize the treatment of the inflammatory phase as rest for the body as a whole and local rest for the spine and affected muscles in the neutral position; heat in moderation for the relief of pain; and prophylactic movements sufficient to prevent fixed shortening of muscles and œdematous stiffness of joints.

TREATMENT IN THE STAGE OF POTENTIAL RECOVERY

Persistent and patient physiotherapy is the keystone of treatment in this stage and the first six months are all-important. The danger is still of doing too much at the beginning and, if the energy and hopes of both patient and physiotherapist are exhausted in this way, it is probable that too little will be done later on. We might compare the treatment of poliomyelitis with a good runner in the mile race who starts fairly gently and speeds up with each succeeding lap, but holds his greatest effort in reserve for the final sprint. To pursue the analogy further, the after-treatment of a simple fracture is comparable to a short race in which the all-out effort must be built up rapidly for the best results. I think it is important for the patient and physiotherapist to adopt the method of the good mile runner in the treatment of poliomyelitis—more especially perhaps the physiotherapist, who is expected nowadays to use intensive treatment for quick results in some conditions and must adjust herself to both gentle and vigorous work from patient to patient during the day.

After the infection in the spinal cord has been overcome the inflammatory œdema subsides and fairly rapid and widespread improvement occurs in the majority of cases. The recovery in this respect is spontaneous and usually complete at three months; but not much earlier except in mild cases. I do not think anything is to be gained by forcing the pace during this period. Weak muscles should be supported against gravity, especially in the case of the shoulder girdle, arm and hand; and sitting up or ambulation without efficient support should not be permitted if this will throw undue strain on trunk and leg muscles. In my view the important procedure at this stage is frequent and carefully graduated exercises with intervals of effective rest.

At this stage vasomotor changes do not seem to give so much trouble as later on; but it is important to keep the paralysed muscles warm and more especially to avoid exposure and chilling during treatment. Hot packs, warm baths or sinusoidal baths seem to be more useful than radiant heat or diathermy. However, hot packs are time-consuming and at some stages it is not practicable to use baths. In these circumstances a radiant heat cradle or short-wave diathermy should be applied over the trunk or proximal part of the limbs in order to raise the temperature of the body and large blood-vessels. It is our experience that heat applied to a cold paralysed periphery is relatively ineffective and of short duration.

I support Seddon's plea for keeping careful record of the voluntary power of the affected muscles from the beginning of treatment and at regular intervals, as well as for the universal adoption of the classification and system of recording recommended by the Peripheral Nerve Injuries Committee of the Medical Research Council.

Our main concern is with the muscles which have sustained loss of neurones due to permanent damage in the anterior horn cells. It is now generally agreed that overstretching due to lack of support or to splinting in the extended position is harmful; but that full-range movements during the course of treatment are valuable both to prevent fixed shortening of the muscles and to stimulate the stretch reflex.

In the majority of cases electrical stimulation is of little value and may take time which could be employed more profitably in active exercises. Seddon is of the opinion that galvanic stimulation is unjustifiable since if the anterior horn cell is dead the axon will not regenerate, whilst if the anterior horn cell survives the electrical excitability of the muscle is normal and the faradic current, if any, should be used. There is no doubt that occasionally electrical stimulation is useful to start a severely paralysed muscle on the road to improvement. Toomey says that weak muscles in which there is also autonomic vascular disturbance are less excitable than normal and that voluntary contraction cannot be obtained in such muscles unless they are kept in good condition (Toomey, 1947). It is possible that this may explain the benefit which appears to follow electrical stimulation in some cases. Weak muscles respond more readily to the galvanic current because of the predominance of denervated fibres and I think there is a place for it in selected cases.

Whilst we are mainly concerned in this stage with the treatment of flaccid paralysis we meet occasionally cases in which the affected muscle appears capable of quite a strong voluntary contraction; but the patient cannot always initiate such contractions during co-ordinated movement. Lack of co-ordination rather than weakness seems to be the main problem. Although the virus has a selective affinity for the anterior horn cells it may affect any part of the central nervous system, or perhaps it is more true to say that the inflammatory oedema consequent upon the infection may give rise to signs in the adjacent afferent and efferent tracts. In some cases the tendon reflexes are increased and there are other signs of spastic paralysis. In my experience these changes tend to improve and seldom complicate the problem in the late stages.

Toomey suggests that muscle imbalance rather than inco-ordination occurs when one muscle is weaker than its antagonist. He suggests that patients with weak muscles tend to substitute others subconsciously and that further disuse atrophy in the weak muscle occurs. Elkins suggests that muscle dysfunction is due to synchronous contraction of agonist and antagonist due to disturbance of the normal mechanism of reflex innervation and he stresses the importance of the co-ordination of muscle function during treatment (Elkins and Wakim, 1947). There seems no doubt that the problems of the so-called muscle spasm and inco-ordination are related but the precise mechanism has not been fully worked out. The practical implication in treatment is that we should train the co-ordination of muscle groups as well as graduate exercises to strengthen individual weak muscles.

Occasionally oedema of a paralysed limb gives rise to difficulty and should be controlled by elevation, massage and an elastic bandage or stocking. Massage is useful to assist the circulation of paralysed limbs, but it is time-consuming and necessary only in exceptional cases.

TREATMENT IN THE STAGE OF CHRONIC DISABILITY

Some time between six months and two years it becomes obvious that no further improvement is likely to be obtained in the weak muscles by graduated exercise. This is always a difficult decision to take and the point is reached so gradually that it is apt to be overlooked with the result that expectant treatment is continued too long with unnecessary financial hardship to the patient. I think a physiotherapist who has been coaxing weak muscles for many months is liable to underestimate the degree of recovery at this stage and consequently it is important for the medical practitioner to check the voluntary power record frequently at this period. Once the decision has been taken that the limit of improvement has been reached beneficial trick movements should be encouraged and surviving muscles developed by intensive exercises to compensate as far as possible for those which are paralysed or permanently weakened. Reconstructive operations call for physiotherapy during convalescence along the well-established lines which need no special comment, but we must always guard against the over-treatment of these patients in the early stages.

Dr. P. Bauwens: Being essentially an infectious disease, the diagnosis of A.P.M. in the acute phase is made entirely on clinical and pathological findings.

Electrodiagnostic methods, which amount to a cross-examination of muscles, study only one aspect (the paralytic aspect) of a complex picture. They are, therefore, of no assistance in differential diagnosis, but as the tragic consequences of this disease are related solely to the paralytic phenomena which persist after the others have abated, it is not surprising that these methods play an important part in establishing a prognosis. The electromyographic observations in particular contribute to this.

In the normal muscle fully at rest, no electrical activity is detected either by means of surface electrodes or concentric needle electrodes inserted into the muscle under investigation. During voluntary contraction, action potentials are produced in the muscular component of active motor units. As the contraction increases in strength the electrical disturbances increase both in quantity and in complexity: in quantity because a larger number of motor units enter into play; in complexity because motor units do not fire off simultaneously. Consequently, the electrical by-products to which each motor unit gives rise interfere with those produced by other motor units. The resulting interference pattern is the rule in normal muscles on moderate and maximal effort. Indeed, single discrete motor-unit activity is difficult to produce in the normal muscles.

Taking silence at rest and interfering activity on maximal effort as criteria of normality, it is possible to observe deviations from these criteria and to discuss their prognostic significance. In motor neurone diseases characterized by a progressive destruction of motor units, spontaneous activity frequently occurs in condemned units. Clinically it is seen as fasciculation while in the electromyograph it gives rise to irregular electrical discharges of moderately high amplitude.

The onset of paralysis in A.P.M. is in many ways the history of a motor-neurone disease telescoped into a very short space of time. It is therefore not surprising that spontaneous motor-unit activity of the fasciculation type should occasionally be encountered in the acute phases. In addition to this many muscles appear to be in a state of hyper-irritability. While not actually the seat of spontaneous discharges when the joints which they actuate are placed in comfortable attitudes, these muscles contract on the slightest provocation. Showers of electrical activity accompany these contractions and although I have no evidence to adduce in support of my contention, I suppose that gross exaggeration of this mechanism is the cause of the "spasm" which is described as a prominent feature in some epidemics. Almost any proprioceptive impulse will evoke an electrical discharge in muscles which exhibit this.

With the destruction of anterior horn cells, the number of motor units which operate during muscular contraction decreases. It follows that during activity fewer action potentials are picked up. In bad cases these are reduced to such an extent that there is no longer any sign of interference and the electrical activity manifests itself as a repetition of discrete diphasic potentials on maximal exertion. This activity is clearly due to motor units which are still operative. Their activity may on casual observation appear normal in every respect, yet it may on closer examination exhibit some characteristics of grave prognostic significance. For reasons not yet explained, when the anterior horns are profoundly affected their cells tend to fire off simultaneously, instead of in random fashion. This results in a synchronization of motor-unit activity throughout the muscle. It can be detected by the use of two concentric needle electrodes inserted into a muscle and connected to a double-channel amplifier. Clemmessen and Buchthal who first drew attention to this particular characteristic of paralysis of medullary origin stress its grave prognostic significance in A.P.M.

Although the denervated motor units obviously can no longer respond to volition, they are still capable of some electrical activity. Whereas in the normal motor unit every muscle fibre contracts simultaneously under the influence of impulses reaching them from the nerve fibre, in the denervated unit the muscle fibres behave as autonomous hyperexcitable individuals which appear to react in a repetitive manner to the presence of small amounts of acetylcholine. This fibrillary activity gives rise to characteristic repetitive low voltage spike potentials of short duration. It is diagnostic of axon degeneration.

Those motor units which regenerate after degeneration give rise to highly polyphasic discharges during the stage which precedes recovery. When these occur in paralysed muscles which have previously been silent except for fibrillation they are of good prognosis.

The fact that moderately early recovery can take place in muscles which have at one time shown a marked degree of denervation lends weight to the recent view that this disease may have a more important peripheral neuropathic aspect as distinct from a purely myelopathic aspect than was hitherto suspected. It seems reasonable to suppose that those cases with a purely neuropathic component have a better chance of ultimate restoration than the myelopathic ones. This hypothesis certainly explains why the synchronized motor-unit activity, which points unquestionably to a medullary involvement, is of such very sinister significance.

In several of those cases which have come under my observation of muscles which had recovered power, there co-existed wasting coupled with absent or diminished reflex action and slight incoordination. The puzzling feature was that both maximal exertion and stimulation of the nerve gave rise to normal muscle action potential measurements and no signs of denervation. To explain this, one has to fall back on the assumption that internuncial fibres have been damaged by the disease.

Although not of prognostic or diagnostic importance, it is interesting to note how rapidly fatigue sets in in paretic muscles and how many patients complain of cramp in the lower limbs when these have been affected. The distribution of these painful localized contractions within a muscle tends to indicate a phenomenon of vascular rather than nervous origin.

Miss D. B. Kidd: In the physical treatment of poliomyelitis I have grouped certain important points under the three usually accepted stages of the disease: (a) the early acute stage; (b) the convalescent stage, and (c) the chronic stage.

The early acute stage is essentially the stage of rest. Rest is particularly important where muscle

tenderness, pain and muscle spasm are present, and especially in these cases it appears to be only adequately achieved by firm support, such as is supplied by well-moulded splints of, for example, plaster or perspex.

Muscle tenderness and spasm are also relieved by heat, which at the same time maintains an adequate circulation. My own experience leads me to the conclusion that wet heat is more efficient than dry heat. Short-wave diathermy and radiant heat have proved disappointing and I rely largely on the use of hot wet packs. For these I use towels wrung out in hot water and wrapped round the limb or part. Each towel is left in contact just so long as it takes to prepare the next, and the whole process is continued for approximately ten to fifteen minutes. When towels are in short supply I use three to four layers of lint, or in the children's ward three or four baby's napkins serve the purpose admirably. These hot packs are repeated two or three times daily and precede any other treatment that is being given. They are continued while muscle tenderness persists, usually not longer than three weeks.

At this stage to prevent stiffness and deformity each joint is put passively through its full anatomical range twice daily. Abnormal range, such as is possible in cases of flaccid paralysis, is carefully avoided.

This treatment is begun early, preferably not later than forty-eight hours after the onset of the disease, and is continued until the acute condition subsides. During this stage assisted active movements may gradually be introduced, but detailed progressive re-education is not instituted until the patient has reached the convalescent stage.

The *convalescent stage* is recognized as the stage of re-education, but a correct balance must be maintained between rest and activity and while paralysis or paresis persists, adequate splinting should be retained between treatments.

Before any detailed re-education can be instituted an accurate test of voluntary power should be made and muscles graded according to their power. These tests are repeated at regular intervals. The first test is best carried out over a few days as the acute symptoms subside.

It is not always easy to recognize when a re-education scheme should be introduced. I have found it wiser at first to underrate rather than overrate the power of a muscle. If then fatigue is not observed and progress is satisfactory, exercises can be stepped up as required. Should fatigue occur they should be cut down or stopped at once.

Re-education at first is confined to localized controlled movements only, after which the re-education of co-ordinated movements is introduced. Such a procedure I have found essential in order to obviate the danger of trick movement which only develops the stronger muscles at the expense of the weaker.

The first essential factor in the re-education of these localized controlled movements is the training of the sense of movement in the mind of the patient. This is best taught by carrying out carefully and slowly the desired movement passively while the patient concentrates on what is being done. An adult patient benefits here by being given a little anatomical knowledge. He may then attempt the movement himself, but where his own power is known to be inadequate the movement must be assisted or even wholly achieved by the physiotherapist, otherwise it will either not be achieved at all and the newly learnt sense of movement will be lost, or it will be achieved by the wrong muscles, a trick action resulting. It is also important to ensure that an adequate range of movement is carried out. The whole of the inner range should be used, the muscle being assisted if necessary to work to its innermost point of contraction.

In order to minimize the muscular effort of group action it is necessary to give firm fixation to the fulcrum of movement and to give adequate support to the part moving. As muscle power improves resistance should be added and the number of times the movement is performed increased.

This technique I use regardless of the method employed for re-education, be it under water, in suspension slings or manually, that is, unaided by apparatus. The latter method I always employ at the outset, as a close watch and even closer "feel" is required by the physiotherapist. Of the remaining two methods I infinitely prefer that of suspension slings. In this way the movement is more precise and trick action less likely to develop. Also it is possible to give the patient sufficient rest periods between movements. I have found the pool becomes tiring after twenty to thirty minutes and in this time it is not possible to give adequate re-education where the paralysis is extensive. I therefore prefer to reserve pool therapy for the re-education of co-ordinated movements.

With regard to resisted movements for the development of muscle power, this too is best achieved manually at first as in the early recovery stages the power of the muscle is found to vary from day to day with the mood and condition of the patient. Also a weak muscle will not be able to take the same amount of resistance when contracting through its inner range as when working in its middle range, and such an adjustment can only be made by the physiotherapist's hands. Later, as strength returns, resistance may be made by other means, either simple tension springs or weights. I prefer a simple system of weights and pulleys as these can be more regularly and carefully graduated and an accurate record of progress can be made. Such a record has more than a technical value for it has an encouraging psychological effect on the patient and consequently helps to maintain his co-operation in what must be a long and tedious process.

The re-education of co-ordinated movement is introduced when the patient can achieve the localized movement with the weakened muscle in the gravity-eliminated position. Once introduced they are used in the scheme of treatment alongside of the localized work. These co-ordinated exercises are aimed first at the retraining of group action, the weakened muscle being made to work not only as a prime mover, but also as a synergist and fixator. Following on this, attention is focused on the function of the part, and exercises are introduced involving two or more joints. At the same time occupational therapy comes into the programme, care being taken that trick action is not developed at the expense of the weakened muscles.

Whenever possible the co-ordination exercises are given as free active exercises. Where, however,

muscle power does not allow of this, pool therapy is the best substitute. Should this not be available spring suspension may be used. This has the advantage over ordinary sling suspension in that movement may now be carried out in any plane.

It should be recognized that where suspension sling or spring therapy is employed any simple apparatus may be used, such as the single or double balkan beam. These can easily be fixed up over the patient's bed in the ward, and in suitable cases arrangements can be made for the patient to carry out periods of exercise on his own during the day. But unsupervised treatment is undesirable in the early stages.

Before leaving the treatment of the convalescent stage I should like to speak for a moment on the importance of retraining the postural sense in the upright position. This is necessary in a great number of patients, but it is to the cases of spinal and abdominal involvement that I wish to draw attention. I have found that patients benefit, even in the most severe cases, by attempting to maintain the sitting posture for a few moments at a time at an early date. I therefore introduce the taking of this position over the side of the bed after two to three months; at first it is only included in the treatment two or three times a week. Adequate support is always given, in some instances the patient being literally held up.

The chronic stage is reached when the patient has ceased to make progress over a period of two to three months, and this may be eighteen months to two years or more from the onset of the disease. It is the stage of residual disability, and fortunately many patients never come to this, making a perfect or almost perfect recovery, and requiring only to be hardened off by class work and occupational therapy before return to a normal life.

The chronic stage concerns those who are to be crippled in some degree for life. When this stage is reached it is essential that patients old enough to understand have their condition clearly explained to them. The right moment must be carefully selected to avoid psychological disturbance and is the responsibility of the medical practitioner. Following on this I have found it essential to make drastic changes in treatment. All localized controlled work is stopped and emphasis is laid not only on the co-ordination work previously instituted, but also on the development of trick action which hitherto has been forbidden. In this way the patient is able to make progress in function and is stimulated to further effort.

To re-educate walking we must frequently use ambulatory splints. There are very few cases who cannot attempt walking. I find it preferable not to introduce it while the patient is still making satisfactory progress in recumbency. When it is eventually introduced it is quite remarkable to note in many cases a distinct improvement in some muscles which had seemingly already reached their maximum power.

The President (Dr. W. S. Tegner) said that he thought Dr. Cooksey's advocacy of moist heat in treatment seemed to give them a rational clue to any value there might be in the Kenny treatment.

Dr. Tegner asked Dr. Bauwens whether in his opinion anterior poliomyelitis was a reversible process and could recovery take place if once an anterior horn cell was knocked out. This was an important point to consider when the value of electrical stimulation in treatment was discussed.

Dr. P. Bauwens replied that, while damage to an anterior horn cell might be permanent, he believed that there was evidence in this disease of lower motor neurone damage without anterior horn cell involvement, and for this type of damage he used the term infantile paralysis.

Dr. J. Barnes Burt: Perhaps one of the chief advances in the treatment of poliomyelitis in the last few years has been the use of the hot pool. In the U.S.A. where this treatment was first in general use, it is considered that hospitalization is shortened by one or two months. The hot pool provides two essential elements for improving the condition of the limbs: (a) Relaxation of muscles; (b) even support of the weakened limbs. Another important factor is the excellent psychological effect. The joy of the children when placed in the hot pool has to be seen to be believed! This factor is, to a certain extent, missed in the Hubbard tank, although the tank has some advantages. It is far cheaper to run, and is not so tiring for the nurses. Special skill has to be exercised by the hydrological nurses. It is quite a different process to assisting passive movement, carried out on a couch, and special training is required. Where one limb is very weak, or has been encased in plaster, Lowman's boards are useful. The temperature of the water ought to be about 98° F., although 102° F. is the optimum for the relaxation of muscles. At a higher temperature than 99° F. the nurses in the pool find it very exhausting, and at this temperature there is less liability for the patient to suffer from thermal debility. If possible all hot pools ought to be provided with a gantry and sling. To carry a paralysed adult, or heavy child, down wet steps, is a great tax on the strength of the nurses, and is apt to frighten the patients.

In the hot pool at Bath, during the last few months of 1947, forty to fifty treatments per week were given to patients in the convalescent stage of poliomyelitis.

Dr. Basil Kiernander said that it was his personal experience that a number of cases of poliomyelitis in which the faradic response of muscles had disappeared had shown, in due course, a return of this faradic response. In these cases, to his mind, it was definitely worth while stimulating the paralysed muscles with interrupted galvanism to keep the muscle fibres well developed in possible regeneration.

He had used short-wave diathermy to the affected muscles for the relief of pain in it and in a number of these cases it appeared to cause considerable relief, but the relief in this way was no higher than for those in which hot packs were employed.

tenderness, pain and muscle spasm are present, and especially in these cases it appears to be only adequately achieved by firm support, such as is supplied by well-moulded splints of, for example, plaster or perspex.

Muscle tenderness and spasm are also relieved by heat, which at the same time maintains an adequate circulation. My own experience leads me to the conclusion that wet heat is more efficient than dry heat. Short-wave diathermy and radiant heat have proved disappointing and I rely largely on the use of hot wet packs. For these I use towels wrung out in hot water and wrapped round the limb or part. Each towel is left in contact just so long as it takes to prepare the next, and the whole process is continued for approximately ten to fifteen minutes. When towels are in short supply I use three to four layers of lint, or in the children's ward three or four baby's nappies serve the purpose admirably. These hot packs are repeated two or three times daily and precede any other treatment that is being given. They are continued while muscle tenderness persists, usually not longer than three weeks.

At this stage to prevent stiffness and deformity each joint is put passively through its full anatomical range twice daily. Abnormal range, such as is possible in cases of flaccid paralysis, is carefully avoided.

This treatment is begun early, preferably not later than forty-eight hours after the onset of the disease, and is continued until the acute condition subsides. During this stage assisted active movements may gradually be introduced, but detailed progressive re-education is not instituted until the patient has reached the convalescent stage.

The convalescent stage is recognized as the stage of re-education, but a correct balance must be maintained between rest and activity and while paralysis or paresis persists, adequate splinting should be retained between treatments.

Before any detailed re-education can be instituted an accurate test of voluntary power should be made and muscles graded according to their power. These tests are repeated at regular intervals. The first test is best carried out over a few days as the acute symptoms subside.

It is not always easy to recognize when a re-education scheme should be introduced. I have found it wiser at first to underrate rather than overrate the power of a muscle. If then fatigue is not observed and progress is satisfactory, exercises can be stepped up as required. Should fatigue occur they should be cut down or stopped at once.

Re-education at first is confined to localized controlled movements only, after which the re-education of co-ordinated movements is introduced. Such a procedure I have found essential in order to obviate the danger of trick movement which only develops the stronger muscles at the expense of the weaker.

The first essential factor in the re-education of these localized controlled movements is the training of the sense of movement in the mind of the patient. This is best taught by carrying out carefully and slowly the desired movement passively while the patient concentrates on what is being done. An adult patient benefits here by being given a little anatomical knowledge. He may then attempt the movement himself, but where his own power is known to be inadequate the movement must be assisted or even wholly achieved by the physiotherapist, otherwise it will either not be achieved at all and the newly learnt sense of movement will be lost, or it will be achieved by the wrong muscles, a trick action resulting. It is also important to ensure that an adequate range of movement is carried out. The whole of the inner range should be used, the muscle being assisted if necessary to work to its innermost point of contraction.

In order to minimize the muscular effort of group action it is necessary to give firm fixation to the fulcrum of movement and to give adequate support to the part moving. As muscle power improves resistance should be added and the number of times the movement is performed increased.

This technique I use regardless of the method employed for re-education, be it under water, in suspension slings or manually, that is, unaided by apparatus. The latter method I always employ at the outset, as a close watch and even closer "feel" is required by the physiotherapist. Of the remaining two methods I infinitely prefer that of suspension slings. In this way the movement is more precise and trick action less likely to develop. Also it is possible to give the patient sufficient rest periods between movements. I have found the pool becomes tiring after twenty to thirty minutes and in this time it is not possible to give adequate re-education where the paralysis is extensive. I therefore prefer to reserve pool therapy for the re-education of co-ordinated movements.

With regard to resisted movements for the development of muscle power, this too is best achieved manually at first as in the early recovery stages the power of the muscle is found to vary from day to day with the mood and condition of the patient. Also a weak muscle will not be able to take the same amount of resistance when contracting through its inner range as when working in its middle range, and such an adjustment can only be made by the physiotherapist's hands. Later, as strength returns, resistance may be made by other means, either simple tension springs or weights. I prefer a simple system of weights and pulleys as these can be more regularly and carefully graduated and an accurate record of progress can be made. Such a record has more than a technical value for it has an encouraging psychological effect on the patient and consequently helps to maintain his co-operation in what must be a long and tedious process.

The re-education of co-ordinated movement is introduced when the patient can achieve the localized movement with the weakened muscle in the gravity-eliminated position. Once introduced they are used in the scheme of treatment alongside of the localized work. These co-ordinated exercises are aimed first at the retraining of group action, the weakened muscle being made to work not only as a prime mover, but also as a synergist and fixator. Following on this, attention is focused on the function of the part, and exercises are introduced involving two or more joints. At the same time occupational therapy comes into the programme, care being taken that trick action is not developed at the expense of the weakened muscles.

Whenever possible the co-ordination exercises are given as free active exercises. Where, however,

muscle power does not allow of this, pool therapy is the best substitute. Should this not be available spring suspension may be used. This has the advantage over ordinary sling suspension in that movement may now be carried out in any plane.

It should be recognized that where suspension sling or spring therapy is employed any simple apparatus may be used, such as the single or double balkan beam. These can easily be fixed up over the patient's bed in the ward, and in suitable cases arrangements can be made for the patient to carry out periods of exercise on his own during the day. But unsupervised treatment is undesirable in the early stages.

Before leaving the treatment of the convalescent stage I should like to speak for a moment on the importance of retraining the postural sense in the upright position. This is necessary in a great number of patients, but it is to the cases of spinal and abdominal involvement that I wish to draw attention. I have found that patients benefit, even in the most severe cases, by attempting to maintain the sitting posture for a few moments at a time at an early date. I therefore introduce the taking of this position over the side of the bed after two to three months; at first it is only included in the treatment two or three times a week. Adequate support is always given, in some instances the patient being literally held up.

The chronic stage is reached when the patient has ceased to make progress over a period of two to three months, and this may be eighteen months to two years or more from the onset of the disease. It is the stage of residual disability, and fortunately many patients never come to this, making a perfect or almost perfect recovery, and requiring only to be hardened off by class work and occupational therapy before return to a normal life.

The chronic stage concerns those who are to be crippled in some degree for life. When this stage is reached it is essential that patients old enough to understand have their condition clearly explained to them. The right moment must be carefully selected to avoid psychological disturbance and is the responsibility of the medical practitioner. Following on this I have found it essential to make drastic changes in treatment. All localized controlled work is stopped and emphasis is laid not only on the co-ordination work previously instituted, but also on the development of trick action which hitherto has been forbidden. In this way the patient is able to make progress in function and is stimulated to further effort.

To re-educate walking we must frequently use ambulatory splints. There are very few cases who cannot attempt walking. I find it preferable not to introduce it while the patient is still making satisfactory progress in recumbency. When it is eventually introduced it is quite remarkable to note in many cases a distinct improvement in some muscles which had seemingly already reached their maximum power.

The President (Dr. W. S. Tegner) said that he thought Dr. Cooksey's advocacy of moist heat in treatment seemed to give them a rational clue to any value there might be in the Kenny treatment.

Dr. Tegner asked Dr. Bauwens whether in his opinion anterior poliomyelitis was a reversible process and could recovery take place if once an anterior horn cell was knocked out. This was an important point to consider when the value of electrical stimulation in treatment was discussed.

Dr. P. Bauwens replied that, while damage to an anterior horn cell might be permanent, he believed that there was evidence in this disease of lower motor neurone damage without anterior horn cell involvement, and for this type of damage he used the term infantile paralysis.

Dr. J. Barnes Burt: Perhaps one of the chief advances in the treatment of poliomyelitis in the last few years has been the use of the hot pool. In the U.S.A. where this treatment was first in general use, it is considered that hospitalization is shortened by one or two months. The hot pool provides two essential elements for improving the condition of the limbs: (a) Relaxation of muscles; (b) even support of the weakened limbs. Another important factor is the excellent psychological effect. The joy of the children when placed in the hot pool has to be seen to be believed! This factor is, to a certain extent, missed in the Hubbard tank, although the tank has some advantages. It is far cheaper to run, and is not so tiring for the nurses. Special skill has to be exercised by the hydrological nurses. It is quite a different process to assisting passive movement, carried out on a couch, and special training is required. Where one limb is very weak, or has been encased in plaster, Lowman's boards are useful. The temperature of the water ought to be about 98° F., although 102° F. is the optimum for the relaxation of muscles. At a higher temperature than 99° F. the nurses in the pool find it very exhausting, and at this temperature there is less liability for the patient to suffer from thermal debility. If possible all hot pools ought to be provided with a gantry and sling. Infantile Cerebral Palsy

By PHILIP RAINSFORD EVANS, M.D., M.Sc., F.R.C.P.

INCIDENCE

THE incidence of infantile cerebral palsy has been estimated by Duryea (1941) to be 50 patients per 100,000 of the population in the United States of America. According to Phelps (1941) the figures are similar in urban and rural districts, and may be expressed as: 7 born each year per 100,000 population:—1 dies in infancy; 2 are mentally defective; 4 are educable, of whom 1 is mildly, 2 moderately, and 1 severely afflicted.

Thus for every 100,000 people there are probably about 30 children who are moderately affected and who need special education and therapy. At this rate London would have to cope with over 2,000 children with cerebral palsy who need these special methods, and perhaps another 3,000 who are so severely handicapped mentally or physically that they need to be cared for in institutions. It must, however, be emphasized that we have no figures upon which an estimate of the incidence in this country can be based. A survey is needed. All one can say at present is that the two residential units open in England accommodate some 50 children, and that the pathetic quest of the parents for adequate treatment for their handicapped sons and daughters is marked by recurring disappointment.

Classification.—Cerebral palsy is a condition arising in early life, due to imperfect development or damage of the central nervous system above the segmental level, and characterized by motor disability. This disability may be associated with spasticity, rigidity, or flaccidity of the muscles, with ataxia, or with involuntary movements.

W. J. Little (1843*b*) gave an excellent description of cerebral palsy in one of his "Lectures on Deformities of the Human Frame" in 1843. In a Paper read to the Obstetrical Society in 1862, he elaborated his early observations (1843*a*) on the association of prematurity and asphyxia with this type of disease. He has received and deserves great credit for his accurate and original observations but it is unfortunate that recognition of his merit has taken the form of a chapter heading: "Little's Disease (Spastic Diplegia)." He did not describe a uniform and clear-cut disease, but an association between certain abnormalities of labour and the newborn period and diverse mental and physical abnormalities seen later in life. Some of the children exhibited spastic diplegia, others paraplegia, hemiplegia, triplegia, fits, mental defect, and involuntary movements. The term athetosis was not invented until 1874.

The classification of these conditions has become so much confused that it is possible for diplegia and paraplegia to be used in the same sense in the same table (Brockway, 1936), while a simple division of cases into spastic and athetoid has been known to arouse in a neurologist the unbecoming passion of anger.

Classification may first be considered topographically. In Table I, diplegia has currently two different meanings, and here we will use the term paraplegia and quadriplegia instead. I will not attempt to defend the logic of this conventional division of paralyses. Starting with monoplegia, a one-stroke, we go on to a half-stroke which is twice as extensive as a monoplegia; a diplegia or two-stroke is actually four times as extensive as a one-stroke but affects twice as many limbs as a half-stroke.

TABLE I.—NOMENCLATURE ACCORDING TO LIMB-INVOLVEMENT

Limbs involved	Neurological Term	American Therapists' Term
 OR 	Monoplegia	Monoplegia
	Hemiplegia	Hemiplegia
	Triplegia	Triplegia
	Paraplegia	Diplegia
	Diplegia	Quadriplegia*

*The term "quadriplegia" is customary, although "tetraplegia" is more in keeping with Greek prefixes of the other types.

We are in more difficulty when we come to disturbance of function (Table II).

TABLE II.—CLASSIFICATION BY DISTURBANCE OF FUNCTION
Neurological Phelps (1938, 1941) and others

Spastic	Spastic
Flaccid or atonic	Flaccid
Rigid (lead pipe)	Rigid (plastic)
Double athetosis	Athetoid { Non-tension Tension
Double hemiplegia }	
Ataxia	Tremor
Chorea	Ataxia
	Chorea

The chief difficulty is to reconcile the neurologists who consider double hemiplegia an important group, and double athetosis to be rare, with those who follow Phelps in classifying 40% of cerebral palsies as athetoid and in paying little attention to double hemiplegia.

The features which distinguish double hemiplegia from spastic quadriplegia are shown in Table III.

TABLE III
Spastic quadriplegia Double hemiplegia

Paralysis symmetrical	Paralysis asymmetrical
Legs worse than arms	Arms worse than legs
Intelligence often slight	Intelligence often normal

Neurologists agree that athetoid movements often appear late in the course of a hemiplegia, particularly in the upper limb. Ford (1946) points out that an extensive lesion of a cerebral hemisphere produced experimentally during the growth period produces defective development of the lenticular nucleus. Phelps, on the other hand, asserts that muscular tension is induced, voluntarily and involuntarily, to suppress athetoid movements. Involuntary movements are unpleasant, we have all seen the "good hand" holding the other and preventing it moving, in unilateral athetosis and occasionally in Sydenham's chorea. I think that if one saw only children under the age of 3 years one would often diagnose double hemiplegia. In older children athetosis is the striking thing, although it may be masked by muscular tension. "Athetoid" is a useful descriptive term directly related to treatment, but the pathology underlying it awaits elucidation.

It might be thought that the behaviour of the plantar reflex would be decisive in indicating which cases were hemiplegia with associated athetosis, and which were primarily athetoid. But the vagaries of this reflex during recovery from acute hemiplegia in childhood indicate that it is not a good differential sign. The reflex in athetoid children is difficult to test satisfactorily, and may be extensor or flexor. Its behaviour, in fact, is like that in the newborn infant, before the extensor reflex has become firmly, although temporarily, established.

Spastic muscles superficially resemble those exhibiting athetoid tension, but a distinction can usually be made on examination. Spastic tension can be overcome only by putting the muscle in a position in which it is not stretched, or by force. Athetoid tension relaxes under verbal persuasion, and gives way to gentleness instead of force. When the child is asleep the muscles are relaxed, and the athetoid limb may be moved in any direction. Even during sleep the spastic muscle tightens when it is stretched. In rare cases of severe athetosis, really amounting to dystonia, muscles may remain tense during sleep.

I have mentioned that the signs in double hemiplegia are not symmetrical. Symmetry need not here be introduced into the description as a separate feature but it is relevant to considerations of aetiology (McGovern and Yannet, 1947).

An indication of the relative incidence of the various types may be obtained by analysis of 115 cases seen by me recently (Table IV). Many presented because of need for special education or treatment, so that the milder types, e.g. the slight hemiplegia or paraplegia which does not prevent a child from going to an ordinary school, are inadequately represented. There are probably some errors in the table as not all patients are easy to classify. I once diagnosed athetosis in a child of 1 year and 4 months. I saw him again one and a half years later and it seemed more likely that he was a hyperactive mental defective, and not an example of cerebral palsy at all.

TABLE IV.—CLASSIFICATION OF 115 CASES OF INFANTILE CEREBRAL PALSY

Type	Number	%
Monoplegia	3	3
Hemiplegia	10	9
Spastic para- or quadri-plegia	43	37
Flaccid quadriplegia	3	3
Athetoid	45	39
Chorea	1	1
Ataxia	4	3
Mixed types	6	5

Most cases fall into the spastic and the athetoid groups, and I propose not to discuss the less common ones further.

ÆTIOLOGY

Except in such studies as Collier's (1899) classical paper on cerebral diplegia, now half a century old, careful pathological investigations correlated with clinical analysis are lacking. I hope Stewart will extend his laborious work, the substance of which was related in his Presidential Address to the Neurological Section in 1942, in this direction.

Purely clinical studies, of which Little's was the first, are more numerous but less convincing. Collier (1924) pointed out that although some factors commonly recur in the case-histories (one may take prematurity as an example) they are not constant and are not, in other children, followed by nervous complications.

Taking the 115 cases (see Table IV) we may note: 8 (7%) had suffered from erythroblastosis foetalis. The neurological sequelæ of nuclear jaundice have been studied by Fitzgerald *et al.* (1939) and by Stiller (1947). In my experience the paralysis in these cases is likely to be severe, and quadriplegic. Chorea or athetosis may develop. Rhesus incompatibility did not appear to be a causative factor in the other cases. Dr. I. A. B. Cathie investigated the mothers of 38 of them without finding evidence of such incompatibility. 4 (3%) were subjects of arrested hydrocephalus, which usually produces spasticity. 3 (3%) had encephalitis, which tends especially to produce hemiplegia or choreo-athetosis. 2 (2%) suffered from hæmorrhagic disease of the newborn, and may have had cerebral hæmorrhages.

Thus the cause of the condition was apparent in 15% of the whole. Considering only the spastic and athetoid groups (79 cases) in the remaining 85%:

There was no familial history and no unusual number of consanguineous marriages in this series. There is a hereditary influence (Bell and Carmichael, 1939; Haldane, 1941) but it is not numerically important.

Prematurity (judged by birth-weight) occurred in 49% of spastics, 32% of athetoids and 8% of a control group of children not suffering from organic nervous disease. Further study of this relationship is necessary.

The incidence of asphyxia and complicated labour was high in the athetoid group.

Table V shows the proportion of affected children who were firstborn, the anæsthetic and forceps rates, and the incidence of neonatal asphyxia of sufficient severity for the parents to remember particulars of it.

TABLE V

	Athetoid	Spastic	Control
Firstborn	73%	33%	24%
Anæsthetic	85%	45%	38%
Forceps	38%	16%	10%
Neonatal asphyxia ..	97%	21%	0%

These results will be reported in greater detail elsewhere, but it is difficult to avoid the conclusion that cerebral anoxia is closely connected with the occurrence of athetosis, while one must accept Freud's (1897) and Collier's (1899, 1924) view that an early defect of neuronal development is probably the cause of spastic paraplegia and quadriplegia.

CLINICAL PICTURE

Characteristically the condition is not diagnosed until the age of 9 months or 1 year. This is partly because the first thing the parents notice to be wrong with the child is that he does not sit up at the right age, and perhaps partly because we use for the examination of these infants a technique which has been designed to show up abnormalities of the adult nervous system.

There may be an early history of a spastic limb or an abnormal posture, of icterus gravis, of atelectasis or cerebral hæmorrhage, of convulsions in the first two weeks of life, but the story is often merely one of delay in the acquisition of motor and postural skills. The child does not sit at the usual age of 6 or 8 months, at 10 months he is seen by a doctor who can find nothing much wrong with him and counsels patience. The first birthday brings comments from the relatives and causes reflection. The infant is taken again to the doctor who advises a consultation or a visit to hospital where the diagnosis is made. Adductor spasm will have developed at this time, and will be apparent when the child is lifted up, but in athetoid cases the characteristic serpentine movements may not be clearly distinguishable from infantile and physiological inco-ordination until the age of two years.

Table VI shows the delay in sitting, walking, feeding, talking and acquiring control of the excretions in the first six years. These figures are taken from examination of the records of 59 children who were being considered for admission to a special school and who were preselected as being the more promising cases of those who were too severely affected to go to an ordinary school.

TABLE VI.—AGE WHEN CHILD LEARNED TO SIT AND WALK WITHOUT SUPPORT, TO USE A SPOON, TO TALK (USING SIMPLE SENTENCES), AND BECOME CONTINENT OF URINE AND FÆCES DAY AND NIGHT

Year of life	1st	2nd	3rd	4th	5th	6th	7th or later	Data incomplete
Sat	7	23	5	11	2	2	6	3
Walked	0	2	6	8	5	6	20	12
Used spoon	0	11	14	10	3	2	9	10
Talked	0	7	13	7	7	4	4	17
No incontinence ..	1	18	8	5	3	3	2	19

Bold figures are definitely abnormal

The state of the muscles and reflexes may be compared with the normal and with the familiar example of anterior poliomyelitis (Table VII).

TABLE VII

Condition	System involved	Voluntary contraction of agonist	Tone, on attempted movement		Effect of concentration	Tendon jerks	Plantar reflexes
			Agonist	Antagonist	Other muscles		
Normal	None ..	N	+	—	Synergy	Good	N
Polio.	L.M.N. ..	0	0	0	0	0	0
Spastic	Pyramidal ..	N	+	+	+ or 0	Good	+
Athetoid	Basal ganglia	0 or ±	±	±	±	Bad	±

N = normal; 0 = nil; + = increase; — = diminution; ± = variable

This is perhaps over-schematic but it may be found a useful summary.

Associated features.—Associated neurological defects are supposed to be common, but I do not find many, except those connected with the organs of special sensation. One does, however, encounter:

Squints: These are very common, and are often variable and may be alternating. The “wandering eye” may stop its peregrinations when general physical treatment has achieved some success, but orthoptic treatment may be needed. Blindness may occur, with or without optic atrophy.

Deafness, particularly to certain tones, is common. Its importance has been emphasized by Phelps (1941).

Speech defects are extremely common. They may be due to: (a) Mental defect; (b) deafness; (c) interference by the disease with normal right- or left-handedness; (d) spasticity of the tongue and other muscles of speech; (e) athetosis of tongue, palate, larynx and particularly respiratory muscles. Anyone who has been in an iron lung will realize how much slow, regular, involuntary respiratory movements interfere with speech; it is much more difficult for the severe athetoid who has to contend with irregular involuntary movements. Speech therapy obviously needs intelligent diagnosis in these cases, as well as great skill and patience.

Epilepsy is fairly common.

Dysphagia and dribbling are troublesome in severe cases.

Hydrocephalus has been mentioned. Microcephaly also may accompany spastic palsies, and with true microcephaly there is of course severe mental defect.

General health.—Little remarked that the sufferer from this condition was often said to be the healthiest in the family. He also noticed that “the frame is often lean and wiry, but not wasted”, which is certainly true of athetoids. Spastic children are often thin and may be wasted, but they do not engage in the activities of the athetoids and may be very fat. Treatment of the obesity may be necessary before they can be taught to walk. Dental caries is often gross and usually untreated.

As might be expected, athetoids need more food than spastics. The latter, with their slow and difficult movements, may suffer from the cold. During the fuel crisis last year, a special school was imperfectly heated, and 10 of the 11 boarders had chilblains, while none of the 8 day-attenders suffered in this way.

Urinary incontinence needs special attention. The main thing is to note the individual patient’s habits and means of expressing the desire to micturate. The mother usually works this out herself. The child should feel secure and comfortable on the toilet seat, so that he may relax and empty the bladder completely. Otherwise he will only pass a small quantity in the lavatory but will flood the bed when he is put back in it. This is not, of course, naughtiness or a desire to attract attention, but is caused by relaxation in comfort with a full bladder.

Psychology.—The psychological aspects of the problem are as important as the physical. One must recognize, and avert or treat apathy, aggressiveness, and lack of confidence. Morale may be boosted by apparently small things, like the provision of a school cap, such

Most cases fall into the spastic and the athetoid groups, and I propose not to discuss the less common ones further.

ÆTIOLOGY

Except in such studies as Collier's (1899) classical paper on cerebral diplegia, now half a century old, careful pathological investigations correlated with clinical analysis are lacking. I hope Stewart will extend his laborious work, the substance of which was related in his Presidential Address to the Neurological Section in 1942, in this direction.

Purely clinical studies, of which Little's was the first, are more numerous but less convincing. Collier (1924) pointed out that although some factors commonly recur in the case-histories (one may take prematurity as an example) they are not constant and are not, in other children, followed by nervous complications.

Taking the 115 cases (see Table IV) we may note: 8 (7%) had suffered from erythroblastosis foetalis. The neurological sequelae of nuclear jaundice have been studied by FitzGerald *et al.* (1939) and by Stiller (1947). In my experience the paralysis in these cases is likely to be severe, and quadriplegic. Chorea or athetosis may develop. Rhesus incompatibility did not appear to be a causative factor in the other cases. Dr. I. A. B. Cathie investigated the mothers of 38 of them without finding evidence of such incompatibility. 4 (3%) were subjects of arrested hydrocephalus, which usually produces spasticity. 3 (3%) had encephalitis, which tends especially to produce hemiplegia or choreo-athetosis. 2 (2%) suffered from hæmorrhagic disease of the newborn, and may have had cerebral hæmorrhages.

Thus the cause of the condition was apparent in 15% of the whole. Considering only the spastic and athetoid groups (79 cases) in the remaining 85%:

There was no familial history and no unusual number of consanguineous marriages in this series. There is a hereditary influence (Bell and Carmichael, 1939; Haldane, 1941) but it is not numerically important.

Prematurity (judged by birth-weight) occurred in 49% of spastics, 32% of athetoids and 8% of a control group of children not suffering from organic nervous disease. Further study of this relationship is necessary.

The incidence of asphyxia and complicated labour was high in the athetoid group.

Table V shows the proportion of affected children who were firstborn, the anaesthetic and forceps rates, and the incidence of neonatal asphyxia of sufficient severity for the parents to remember particulars of it.

TABLE V

	Athetoid	Spastic	Control
Firstborn	73%	33%	24%
